The presence of the 160-min solar oscillation originally discovered in the Crimea and observed in phase coherence during the past few years both in the Crimea and at Stanford was looked for using a superposed epoch analysis of the data processed thus far (5 days). Figure 4 shows the result of this analysis, together with the sine wave which would be expected by extrapolating the phase and amplitude according to the average of the Crimean

**Fig. 4** The superposed epoch analysis of a data sample extending over 5 days (45 periods of 160 min). The points represent the South Pole data, and the solid line is the average based upon the observations obtained at the Crimean Observatory and Stanford.

and Californian results. The present result seems to be consistent with the latter. However, note that following a recent study of error analysis of superposed epoch procedure by Forbush *et al.*<sup>30</sup>, standard methods of assigning statistical uncertainties may be not valid in this case.

## Discussion

As we have analysed only part of the data processed so far, it would be premature to undertake a comprehensive discussion of theoretical implications concerning, for example, the depth of the convective zone, helium abundance, or other solar parameters. We have, therefore, only presented observational results which can be regarded as definitive:

(1) Although the 160-min oscillation, in phase with the wave expected from the latest Russian and American results, has been detected, further analysis is required to determine its significance.

(2) The power in the 5-min range is resolved into many equidistant peaks separated by 68  $\mu\text{Hz}$ . The splitting of these peaks,

which is different for even and odd lines, indicates that global modes with  $l$  values of 0, 1, 2 and 3 have been identified.

(3) These global solar oscillations are not overstable, but are spasmodically excited, with a damping time of about 2 days ( $Q = 600$ ).

(4) Comparison between theoretical and observed frequencies of a large number of different modes has made it possible to reduce the uncertainty in the specification of the order of the spherical harmonics to unity.

These results are very encouraging for future astronomical research at the South Pole.

This work was supported by the NSF's Division of Polar Programs under grant DPP-7822267. Assistance in the field was provided by Lyman Page Jr and Jon Towle. Numerous individuals associated with the US Antarctic Research Program in different capacities provided logistical help. We especially thank Robert Pfeiffer, Arthur Smith, Don McCauley, Max Azouit, Jean-Francois Manigault and Alex Robini for technical assistance and Dermott Mullan for helpful discussions.

# Is the Sun helium-deficient?

J. Christensen-Dalsgaard\* & D. O. Gough†

*The recent observations of solar 5-min oscillations of low degree agree approximately with the predictions of a standard solar model with normal abundances of helium and heavy elements. Much of the apparent discrepancy noticed when the observations were first announced was a result of having neglected the influence of the Sun's atmosphere in the normal mode analysis of the theoretical models. Our standard solar models are not in perfect agreement with observation, but it seems that major modifications will not be necessary to remove the remaining small discrepancies.*

CLAVERIE *et al.*'s<sup>1</sup> announcement of the resolution of a sequence of peaks in the power spectrum of whole-disk Doppler observations of the Sun, with frequencies in the range 2–4 mHz, produced an immediate discussion of the implications regarding the Sun's internal structure<sup>2</sup>. The peaks were interpreted as being the result of groups of  $p$  modes of high order, of alternately odd and even degree<sup>2</sup>. Direct comparison of the observed mean spacing between the peaks with predictions from a sequence of three solar models having different internal compositions<sup>3</sup> gave precise agreement only when the internal abundances  $Y$  and  $Z$  of helium and heavy elements were rather low ( $Y = 0.19$ ,  $Z = 0.004$ ). A similar result seemed to be true of a sequence of models studied earlier by Iben and Mahaffy<sup>4</sup>, although in this case it was necessary to extrapolate the composition. However, the discrepancy between observation and the 'standard' models, with  $Z = 0.02$  and  $Y = 0.25$ , was  $< 2\%$ , and without careful consideration of the uncertainties in both theory and observation it could not be concluded that the Sun is necessarily deficient in helium and heavy elements.

Nevertheless, there has already been some discussion of the implications of such a postulate<sup>5</sup>.

The observations of Grec *et al.*<sup>6</sup> have confirmed the original results and have provided us with more accurate and detailed knowledge of the oscillation frequencies. We report here a further theoretical study of the 5-min modes, in the adiabatic approximation, and compare the results with the new observations. Although agreement is not perfect, we find no reason to conclude that the abundances  $Y$  and  $Z$  are surprisingly low.

## Observations

Both Claverie *et al.* and Grec *et al.* measured the shift in a spectrum line in integrated sunlight, and the time dependence of the shift was analysed. In particular, power spectra of the data revealed almost uniformly spaced peaks in the range 2–5 mHz. Similar observations had been made before<sup>7–9</sup>, and although there is a strong hint of discrete peaks in the results of Grec and Fossat<sup>8</sup>, they were never unambiguously resolved, partly because the periods of observation were too short<sup>10</sup>.

The most accurate observations are those of Grec *et al.*<sup>6</sup>. These were made at the South Pole, where the Sun can be seen continuously for long periods of time. The results have not yet been fully analysed, but a power spectrum of 120 h of continuous data is available. In agreement with previous observations<sup>1,7-9,11</sup>, there is a concentration of power near 3 mHz. Moreover, almost all that power is contained in discrete peaks, whose mean spacing in the range 2.4–4.7 mHz is half of 136.0  $\mu$ Hz.

### Interpretation of the observations

We accept that the direct cause of much of the observed power is an oscillation of the Sun that can be represented well by a superposition of linear normal modes. Because the observations integrate light from the entire solar disk, the measurements are sensitive only to modes of low degree. Consequently the modes are probably  $p$  modes of high order, because no solar  $f$  or  $g$  mode of low degree has a frequency as high as 2 mHz.

The frequencies of adiabatic  $p$  modes of low degree  $l$  and high order  $n$  are given approximately by<sup>12</sup>

$$\nu_{n,l} \approx (n + \frac{1}{2}l + \varepsilon)\nu_0 - [l(l+1) + \delta]A\nu_0^2\nu_{n,l}^{-1} \quad (1)$$

where

$$\nu_0 = \left(2 \int_0^R c^{-1} dr\right)^{-1} \quad (2)$$

and  $\varepsilon$ ,  $\delta$  and  $A$  are other constants of the equilibrium solar model. Here  $c$  is the adiabatic sound speed in the equilibrium model,  $r$  is a radial coordinate and  $R$  is the radius of the Sun. The approximation was derived assuming that  $l \ll n$ , and for such modes it provides a good representation of the numerical calculations<sup>10</sup>. The second term is a relatively small correction to the first. It therefore follows that sequences  $\nu_{n,l}$  with fixed  $l$  and varying  $n$  are approximately uniformly spaced with separation close to  $\nu_0$ , that two such sequences with different  $l$  have almost coincident frequencies provided both values of  $l$  are either odd or even, and that the frequencies of modes with odd  $l$  lie approximately midway between those of modes with even  $l$ . The frequencies thus fall into almost uniformly spaced groups, which we label with  $i = 2n + l$ .

Theoretically one would expect modes with high  $n$  and low  $l$  to be excited to amplitudes that on average are roughly independent of  $l$  at fixed  $\nu_{n,l}$  and there is some observational evidence that this is so<sup>10</sup>. Consequently each peak in the observed power spectra should contain contributions from several modes with almost identical frequencies. Thus the value of 136.0  $\mu$ Hz reported by Grec *et al.*<sup>6</sup> for twice the mean spacing between the peaks in their power spectrum represents approximately the spacing between a sequence of eigenfrequencies at fixed  $l$  and varying  $n$ . As  $l$  increases, so does the second term in equation (1), which destroys the correspondence between frequencies of modes with different  $l$ . However, once  $l$  is large enough for the divergence to be substantial, the sensitivity of the observations is too low for it to matter. Indeed, theoretical estimates<sup>10</sup> suggest that the observed signal is dominated by contributions from only those modes with  $l \leq 3$ , and that the expectation  $\bar{\nu}_i$  of the peak frequencies is approximately

$$\bar{\nu}_i = \begin{cases} 0.51 \nu_{n,0} + 0.49 \nu_{n-1,2} & i \text{ even} \\ 0.87 \nu_{n,1} + 0.13 \nu_{n-1,3} & i \text{ odd} \end{cases} \quad (3)$$

The observations of Grec *et al.*<sup>6</sup> confirm this interpretation. It has been possible to resolve structure in the major peaks, which presumably arises from the presence of modes with slightly different frequencies. To reduce noise and the effects of interference, Grec *et al.*<sup>6</sup> performed a superposed frequency analysis on the spectrum, by dividing the spectrum into segments of length 136.0  $\mu$ Hz and adding the segments of spectrum. The result is shown in their Fig. 2. Although this procedure does not take account of the nonlinearity of the dependence of  $\nu_{n,l}$  on  $n$ , the separation of each peak into two main components is clear and the relative power within each of those components is roughly in accordance with theoretical predictions.

### Oscillation eigenfrequencies and the influence of the atmosphere

Oscillation eigenfrequencies of the solar models discussed in ref. 3 and some models of Christensen-Dalsgaard<sup>13</sup> have been computed as described in ref. 10. The most important difference between these computations and those discussed in ref. 3 is that here some account has been taken of the solar atmosphere.

The influence of the atmosphere is important only when the oscillation frequency  $\nu$  is comparable with Lamb's<sup>14</sup> acoustical cutoff frequency  $\nu_c = \gamma g/4\pi c$ , which is the minimum frequency at which acoustic waves can propagate vertically in the atmosphere. Here  $\gamma$  is the adiabatic exponent ( $\partial \ln p / \partial \ln \rho$ ), where  $p$ ,  $\rho$  and  $g$  are pressure, density and specific entropy, and  $g$  is the gravitational acceleration. In the solar atmosphere,  $\nu_c \approx 5$  mHz. Provided  $\nu < \nu_c$ ,  $p$  modes are reflected by an evanescent region that includes the atmosphere, and are thus confined to the solar interior. The lower the frequency, the deeper the level at which reflection takes place. Thus when  $\nu < \nu_c$ , reflection occurs so deep in the Sun that the modes are almost unaffected by the presence of the atmosphere. Neglecting the atmosphere in the computations reported in ref. 3, for example, introduces errors in the frequencies stated explicitly in that paper that are no more than about a part in  $10^5$ .

When  $\nu$  is comparable with  $\nu_c$ , the inertia of the atmosphere is an appreciable fraction of the total mass above the reflecting region. In this case the atmosphere introduces a phase shift in the spatial oscillation of the eigenfunction, and so changes the frequency. It is only when  $\nu$  is quite close to  $\nu_c$  however, that the detailed structure of the atmosphere is important. Otherwise the atmosphere moves almost hydrostatically, and its influence on the phase shift depends only on its mass, which is directly related to the equilibrium photospheric pressure.

We substantiate the discussion above by considering a plane-parallel polytropic layer under constant gravity, supporting an isothermal atmosphere of the same composition. The polytrope is taken to have the structure

$$p = p_0 z^{m+1}, \quad \rho = \rho_0 z^m, \quad z_{ph} \leq z \leq Z \quad (4)$$

where  $z$  is a vertical coordinate measured downwards, and  $p_0$ ,  $\rho_0$  and  $m$  are constants. The isothermal atmosphere in  $(-\infty, z_{ph})$  is determined by requiring that temperature and pressure, and hence density, are continuous at the photosphere  $z = z_{ph}$ .

The horizontal wavelengths of the solar modes of low degree are much greater than the scale height in the atmosphere. Therefore, to determine the influence of the atmosphere on the eigenfrequencies, we need only consider purely vertical oscillations. We assume a rigid base at  $z = Z$ , and select those modes with an energy density that tends to zero as  $z \rightarrow -\infty$ . Thus we are ignoring the potential influence of the corona, or nonlinearities in the upper atmosphere<sup>15-17</sup>.

The analysis is a straightforward generalization of that presented by Lamb<sup>14</sup>. The eigenfrequencies  $\nu_n$  of high order  $n$ , satisfying  $2\pi n \gg m^2$ , are given by

$$\nu_n \approx (n + \frac{1}{2}m - \frac{1}{2})\nu_0 - \frac{(4m^2 - 1)\nu_0^2}{8\pi^2\nu_n} - \frac{\nu_0}{\pi} \tan^{-1} \Phi_m(\alpha_n \lambda_n), \quad (5)$$

where

$$\Phi_m(\alpha, \lambda) = \frac{J_{m+1}(\lambda) - \alpha J_m(\lambda)}{Y_{m+1}(\lambda) - \alpha Y_m(\lambda)}$$

$$\lambda_n = (m+1)x_n, \quad \alpha_n = x_n^{-1} - (x_n^{-2} - 1)^{1/2}, \quad x_n = \nu_n/\nu_0 \quad (6)$$

and the characteristic frequency  $\nu_0$  is now defined by

$$\nu_0^{-1} = 2 \int_0^Z \left( \frac{\rho_0}{\gamma p_0 z} \right)^{1/2} dz; \quad (7)$$

$J_m$  and  $Y_m$  are Bessel functions of order  $m$ . If the isothermal atmosphere were replaced by a rigid lid of the same mass, the

$Y$  and  $Z$  are the initial abundances by mass of helium and heavy elements;  $D$  is the present depth of the convection zone. CS refers to the tables of Cox-Stewart<sup>23</sup>, CRS to Carson (unpublished, but see ref. 24) and CT to Cox-Tabor<sup>25</sup>; the L or S refers to linear or spline interpolation in the tables.  $M$  is the number of mesh points between the centre and the photosphere of the model. Electron screening was taken into account in computing nuclear reaction rates only in models 1–4 and H. An evolutionary calculation was not performed for the chemically homogeneous model H; the initial helium abundance of that model was estimated by homology scaling from its present value of 0.303. The mean frequency separation  $\Delta\nu$  is twice the mean separation, in the range 2.3–4.1 mHz, between the peaks in the power spectrum of an ensemble of all the modes. The mean separations between neighbouring  $l=0$  and  $l=2$  eigenfrequencies and between neighbouring  $l=1$  and  $l=3$  eigenfrequencies of models A, B and C are listed in the last two columns, and are averaged over the same frequency range as  $\Delta\nu$ . The mean separation between neighbouring  $l=0$  and  $l=4$  eigenfrequencies of model A in that range is 35  $\mu$ Hz. The expectations of the relative power in the peaks of a power spectrum produced by modes of different degree can be obtained from ref. 10. These are 0.56, 1.0, 0.54, 0.06 and  $2 \times 10^{-3}$  for  $l=0, 1, 2, 3$  and 4 respectively. Frequencies of dipole modes with frequencies near 2.4 and 4.0 mHz are listed in columns 8 and 9. For model C these frequencies† are  $\nu_{17,1}$  and  $\nu_{29,1}$ .

eigenfrequencies would still be given by equation (5), but with  $\alpha_n = \frac{1}{2}x_n$ . If the atmosphere were ignored entirely, and the lagrangian pressure perturbation were assumed to vanish in the photosphere, then  $\alpha_n = 0$ . Replacing the atmosphere by a polytrope of index  $m$  reduces the equilibrium model to a complete polytrope; in that case the last term in equation (5) is removed, yielding what is essentially Lamb's<sup>14</sup> result. Note that in the limit of small  $x_n$ ,  $\alpha_n = \frac{1}{2}x_n$  and the leading terms in the expansions of  $J_{m+1}(\lambda_n)$  and  $\alpha_n J_m(\lambda_n)$  cancel in equation (6). Thus to leading order, the isothermal and polytropic atmospheres and the rigid lid all yield the same eigenfrequencies.

The result of ignoring the atmosphere entirely is to overestimate the eigenfrequencies by

$$\delta\nu_n = \pi^{-1} \nu_0 [\tan^{-1} \Phi_m(\alpha_n, \lambda_n) - \tan^{-1} \Phi_m(0, \lambda_n)] \quad (8)$$

When  $x_n$  is small this reduces to

$$\delta\nu_n \approx \nu_0 [\Gamma(m+1)\Gamma(m+2)]^{-1} (\frac{1}{2}\lambda_n)^{2(m+1)} \quad (9)$$

where  $\Gamma$  is the gamma function, which shows the increasing importance of the atmosphere as the frequency rises.

We can use equation (8) to obtain a rough estimate of the error in the mean frequency separation introduced by ignoring the atmosphere. If the mean is evaluated between  $\sim 2$  and 4.5 mHz, and  $m \geq 2$ , the result is  $\sim 1$   $\mu$ Hz, and depends only weakly on  $m$  and the precise frequency range over which the mean is evaluated. This estimate is comparable with the difference between the mean separation originally obtained by Claverie *et al.*<sup>1</sup> and the mean that can be deduced from equations (3) and the values quoted for the standard solar model in ref. 3. This justifies our repeating the theoretical eigenfrequency analysis with the atmosphere included.

Equation (8) cannot be used to correct the frequencies in refs 3 and 4, because the Sun is neither plane parallel nor polytropic. It is easy to show that even though the solar atmosphere is thin compared with its radius, in the limit  $x_n \rightarrow 0$  a geometrical correction is introduced into equation (9) which is of the same order as the value derived here. Indeed, the difference between our new results and those of ref. 3 obey a power law when  $\nu \leq 2$  mHz, with exponent  $2(m+1) = 8.6$ , but with a coefficient considerably greater than that given by equation (9). For higher values of  $\nu$ , the numerical results and the plane-parallel theory agree more closely.

## Mean frequency separation of modes

The mean frequency separation between groups of modes was computed in the range 2.3–4.1 mHz, using equation (3) to determine the mean peak positions. The frequency range was chosen to correspond approximately to that within which

Claverie *et al.*<sup>11</sup> could resolve discrete peaks. The mean separations between the peaks with odd  $l$  and with even  $l$  were computed separately; in all the cases we investigated the two values differed by no more than 2 parts in  $10^4$ . The values in Table 1 are averages of the two values and therefore represent twice the mean spacing of the peaks in a power spectrum of an ensemble of all the oscillations.

Model A was computed in the standard way from the zero-age main sequence. In models B and C, which have low initial abundances of heavy elements, the surface was assumed to have been contaminated continuously by accreted material during evolution, at a rate chosen to give  $Z = 0.02$  throughout the convection zone at present. In all cases an atmosphere in hydrostatic equilibrium with the  $T$ - $\tau$  relation of the Harvard-Smithsonian Reference Atmosphere<sup>18</sup> out to  $\tau = 10^{-4}$  was added, as described in ref. 10. The outer boundary condition—that the lagrangian pressure perturbation vanishes—was applied at  $\tau = 10^{-4}$ . Included for comparison is model A\*, which is simply model A with the outer oscillation boundary condition applied at the photosphere, as in ref. 3.

Four other so-called standard models are included in Table 1, to give some idea of the sensitivity of the results to uncertainties in the theory. These are models 1–4 of ref. 13. They all have  $Z = 0.02$ , and differ from each other through the use of different opacity tables, or a different number of mesh points. Electron screening was taken into account in computing the nuclear reaction rates, which was not the case for models A, B and C, and a more accurate numerical scheme was used.

## Comparison of theory with observation

Given a sequence of solar models, one can attempt to find by interpolation a model which best fits the data. First, the frequency separation is interpolated, which should give sufficient information to identify the modes, and then the frequencies themselves can be used.

The original attempt to do this<sup>2</sup> took account of only the frequency separation, because the observed frequencies were not available<sup>1</sup>. Interpolation was essentially between models A, B and C, except that the oscillation boundary condition had been applied at the photosphere. This overestimated the mean theoretical separations by  $\sim 1.5$   $\mu$ Hz for models A and B and 1  $\mu$ Hz for model C, and led to the tentative conclusion that a model close to model B was preferred. However, the reduction of the theoretical eigenfrequencies that has resulted from including the atmosphere, and the slight upward revision of the estimate of the actual frequency separation by the South Pole measurements<sup>6</sup>, have now brought the standard model into closer agreement with observation. Interpolation with respect to

frequency separation alone suggests a model between models A and B, but closer to model A.

The superposed frequency analysis of Grec *et al.*<sup>6</sup>, summarized in their Fig. 2, enables us to identify the modes. By comparison of the relative power within the peaks and the peak separations with the theory summarized in ref. 10 and Table 1, it is evident that the peaks on the left result from modes of odd degree and those on the right from modes of even degree. Note that there is even a hint of the  $l=4$  modes about 35  $\mu\text{Hz}$  below the radial modes. Thus it has been possible to identify the peaks in the power spectrum of the observations at, for example,  $\nu=2.426$  and 4.057 mHz, as modes with  $l=1$  (E. Fossat, personal communication); and we deduce that these modes are of the order of  $n=16$  and 28 respectively. Note, however, that the frequencies of these modes cannot be reproduced by interpolation between models A and B. Extrapolation beyond the standard model to one slightly richer in helium and heavy elements reduces the discrepancies, but perfect agreement is not possible.

### Other solar models

It is not possible to fit all the observations with the eigenfrequencies of a model interpolated in or extrapolated from the sequence A, B, C. However the variations amongst models 1–4 seem to be sufficiently great to suggest that agreement could be achieved with a model that does not differ substantially from our standard. That does not necessarily imply that such a model is a good representation of the Sun. There may be other quite different models which could reproduce the observed frequencies equally well.

In particular, we consider the transient-mixed model that was discussed by Dilke and Gough<sup>19</sup> as a potential explanation for terrestrial glaciation and the low solar neutrino flux. Unfortunately we do not have sufficient information to calculate eigenfrequencies, but we do have the integral in equation (2) evaluated between  $r=0$  and the radius in the radiative interior within which 98% of the mass is contained. Though  $\nu_0$  is not equal to the frequency separation  $\Delta\nu$ , we have found in other models that its variation follows that of  $\Delta\nu$  quite closely. Therefore we have estimated  $\nu_0$  for the transient models as follows.

We selected three values of the time  $t$ . The first,  $t_1$ , was 4,700 Myr, immediately before a phase of mixing; the second,  $t_2$ , was 2 Myr later, which is near to the luminosity minimum; and the third,  $t_3$ , was 5 Myr after  $t_1$ , which is roughly when the luminosity and radius first return to values close to those at  $t_1$ . At each time the radiative interior was scaled homologously, varying  $Y$  at fixed  $Z$  by such an amount as to bring the model to the current solar luminosity. Model envelopes with the solar photospheric radius and the same composition as the unburnt region of the scaled interior were then fitted to the interior, by insisting that the mass and temperature be continuous at the fitting radius. A further small homologous scaling was then necessary to bring the total mass of the entire model to the solar value. The remainder of the integral in equation (2) could then be computed.

During the transient mixing phase of a single model, the luminosity and radius vary. The decrease in temperature, and consequently sound speed, outweighs the smaller relative

decrease in radius, and causes  $\nu_0$  to decrease. However, when three different models each having the same luminosity and radius at the different epochs  $t_1$ ,  $t_2$ , and  $t_3$  are compared, the reverse is true. The values of  $\nu_0$  at  $t_2$  and  $t_3$  were found to be 1.2 and 0.7% greater than the value at  $t_1$ . We conclude that the frequency separation  $\Delta\nu$  has a similar variation.

As a second example we consider a chemically homogeneous solar model in thermal balance, model H. We computed this model to see whether  $g$  modes of low degree and low order could have periods close to 160 min. This particular model, whose properties are summarized in Table 1, has modes  $g_2(l=1)$  and  $g_4(l=2)$  both with periods close to 150 min, and a relatively minor change of parameters could no doubt change them to 160 min. The low degree 5-min  $p$  mode eigenfrequencies are hardly distinguishable from those of model A.

### Conclusion

Approximate agreement between the eigenfrequencies of a standard solar model and the observations of Grec *et al.*<sup>6</sup> has been found in the frequency range 2.3–4.1 mHz. Thus there seems to be no evidence from the whole-disk observations of 5-min oscillations that the solar structure is very different from that of a standard model. Moreover, models with low abundances of helium and heavy elements are incompatible with observation.

The frequencies discussed here contain enough information to differentiate between the models in Table 1 and the real Sun. Therefore we know that none of our models is exact. Small changes in the physics could possibly improve the agreement. In particular, our equation of state may be too inaccurate. Moreover, there have been revisions in opacities and nuclear reaction rates since the models were computed<sup>20</sup>, and when these are taken into account the discrepancies may disappear. Nevertheless, the relative insensitivity of the frequencies to considerable changes in structure, as illustrated by the properties of the mixed models, has suggested that agreement might also be achieved with models rather different from the standard.

To differentiate between the models it may be necessary to seek other measures. For example, only those models with convection zones as deep as  $\sim 2 \times 10^5$  km are compatible with observations of the 5-min oscillations of high degree<sup>21,22</sup>. Thus the chemically homogeneous model H seems to be ruled out. Another quantity that might be measurable is the buoyancy frequency  $N$  beneath the convection zone which controls the  $g$  mode frequencies. Unfortunately, no solar  $g$  mode has yet been identified. However, there is some influence of  $N$  on the  $p$  modes of low degree, especially those that are of low order and which do seem to be present in the whole-disk power spectrum<sup>6</sup>. The data currently available are too noisy to determine the frequencies of the low-order modes precisely, but further analysis of the data obtained by Grec *et al.*<sup>6</sup>, and possibly longer observations of the same type, may make it possible. Then we shall be in a better position to judge the models.

We thank E. Fossat and A. B. Severny for conversations and correspondence. J. C.-D. thanks Aarhus Universitet and Statens naturvidenskabelige Forskningsraad of Denmark for financial support.

# The constancy of the solar diameter over the past 250 years

John H. Parkinson\*, Leslie V. Morrison† & F. Richard Stephenson‡

*Reconsideration of meridian circle observations with analysis of transits of Mercury and durations of total solar eclipses indicate that there has been no detectable secular change in the solar diameter during the past 250 yr.*

ALTHOUGH the output of energy by the Sun is generally assumed to be produced entirely by nuclear processes in the core, experiments to detect the neutrino flux yield only about one-third of the expected value. Among the many ingenious suggestions that have been made to resolve this apparent discrepancy<sup>1</sup> is the recent claim that observational evidence from about 1840 suggests that the Sun's radius is shrinking at the considerable rate of about 0.1% per century<sup>2</sup>. The gravitational energy released in this contraction of the Sun, or at least of the outer layers, would then supplement the Sun's luminosity from nuclear reactions.

The brightness of the Sun depends principally on the core temperature so that, in contracting models of the Sun, the core temperature would need to be reduced to bring the predicted brightness of the Sun into agreement with observation. Such a change would also lower the predicted neutrino emission, possibly to the extent of being consistent with the observed rate. This would remove a major stumbling block in modern astrophysics. Only a small fraction of the Sun's mass could be involved in such a gravitational contraction as a uniform contraction of the entire Sun at the rate suggested would increase the luminosity to  $10^2$ – $10^3$  times its present value.

Here we investigate the reality of the observed contraction of the solar diameter and show that it is based on a misinterpretation of the meridian circle observations used. A more careful analysis, combined with two other methods of investigation, show that there has been no detectable secular change in the Sun's diameter since at least AD 1700.

## Meridian circle measurements

One of the earliest tasks of the Royal Observatory at Greenwich was to measure the position of the Sun in the sky. Using a meridian circle, the times at which the leading and following edges crossed the meridian were noted and the angles from the zenith to the upper and lower limbs were measured. By averaging these pairs of measurements the Sun's position could be obtained, whereas subtraction gives the apparent horizontal and vertical solar diameters.

Analyses of meridian transit measurements for periodic changes in the diameter have produced inconclusive results<sup>3</sup>. There have, however, been reports of secular trends found in the measurements; for example, a horizontal semi-diameter decrease of 0.01 arcs per year from 1890 onwards has been reported<sup>4</sup>. Recently Eddy and Boornazian<sup>2</sup> claimed to find a

Fig. 1 Annual mean values of the Sun's horizontal ( $h$ ) and vertical ( $v$ ) semi-diameters derived from meridian circle observations made at Greenwich<sup>2</sup>. The most reliable results are joined by solid lines and the less reliable ones by dashed lines.

**Fig. 2** *a*, Mean horizontal semi-diameter for the seven regular observers between 1915 and 1940 showing an apparent decrease of 0.01 arc s per year. *b*, Individual annual means for the seven regular observers. Five observers: W,  $\square$ ; H.A., —; R.C., ---; L.S., - - -; H.B.,  $\Delta$  give consistent results, whereas G.R.,  $\circ$  and G.W., + show erratic changes. *c*, The fraction of measurements made each year by G.R. and G.W. As the fraction increased, so the semi-diameter seemed to decrease.

similar trend in the horizontal diameter and about half that rate in the vertical diameter, the evidence for both trends commencing in 1836. As such a significant change would have profound implications for the evolution of the Sun, it warrants further study using other techniques.

Such analyses must be complicated by the instrumental changes at Greenwich since 1836. In 1851, 'Airy's telescope' replaced Troughton's instrument<sup>5</sup>. Figure 1 shows the variation in the annual mean horizontal and vertical semi-diameters derived by Eddy and Boornazian. There is a clear discontinuity in the measurements of the vertical semi-diameter coinciding with the change of telescope showing that the measured

diameter depends crucially on the instrument used. After Airy's instrument had been in service for only one year, it was stated that "no other instrument... can be compared with this for steadiness and accuracy of adjustments or for the accuracy of results"<sup>6</sup>.

As the horizontal measurements were made by noting the length of time taken for the Sun to cross a wire in the eyepiece of the telescope, the measured horizontal diameter depends on both the clarity of the image formed and the accuracy with which the transit time could be measured. Before 1854 the observer watched the Sun while listening to the ticking of a pendulum clock. The precise time at which the Sun crossed the meridian was then interpolated mentally between two successive ticks. In 1854 this crude 'eye and ear' method was replaced by a chronograph, which had the advantage of recording the time automatically. Again, after only one year the observations were judged to be "... indisputably of a higher order of excellence than those formerly made by the ordinary method of eye and ear"<sup>7</sup>. The horizontal semi-diameters in Fig. 1 show a clear discontinuity when the observing method was changed.

The telescope objective glass was repolished in 1891 and again in 1906 (ref. 8) which may have altered the definition of the image and hence the apparent diameter of the Sun. In 1915 the 'impersonal micrometer' was fitted and again this may have affected the horizontal diameter measurements. Observations with Airy's telescope ceased in 1953 when the reversible transit instrument came into operation at Herstmonceux.

A high degree of skill and dexterity were required to operate Airy's meridian circle, and, from its early days, the influence of observer bias was recognized<sup>3,9-11</sup>. In particular, Thackeray demonstrated that each observer had a personal bias which was maintained consistently throughout his observing career. For the nine observers in the period 1861-83, the range of career means was as much as 4.8 arc s for the vertical diameter and 2.2 arc s for the horizontal diameter.

Generally, such personality effects would be expected to increase the scatter in the results, as happens for the data after World War II when as many as 14 observers, most with little or no previous experience, made measurements. The period from the introduction of the impersonal micrometer to 1940 shows a decrease of  $\sim 0.02$  arc s  $\text{yr}^{-1}$  in the mean horizontal semi-diameter. During this time there were seven regular observers, five of whom reported self-consistent annual means with no apparent trends. The other two observers exhibited strong, erratic personal biases, as shown in Fig. 2. As the number of observations made by these two individuals increased through the early 1920s, so the resultant mean diameter based on all the observers decreased, giving a spurious trend.

The observational reports from Greenwich show that weather and seeing conditions were often far from ideal with many comments such as 'through cloud', 'unsteady', 'ill defined', 'poor image', 'limbs boiling', 'definition extremely bad', and so on.

**Fig. 3** Apparent changes in the semi-diameter of the Sun (arc s) deduced from transits of Mercury ( $\bullet$ ) and total solar eclipses ( $\circ$ ). The zero point corresponds to 959.63 arc s. The half-bar lengths are the standard deviations of the distributions, the standard errors of the means lie in the range  $\pm 0.1$  to  $\pm 0.2$  arc s. The dashed line was deduced by Eddy and Boornazian<sup>2</sup> from horizontal meridian circle observations in the period 1836-1953 and has been adjusted for irradiation.

These grave difficulties show that meridian circle observations are unsuitable for investigating possible changes in the solar diameter. We now discuss other, more accurate methods which have the advantage of covering a longer time span and are not so dependent on the defects of the instrument used.

## Transits of Mercury

Observations of the time taken for the planet Mercury to transit across the face of the Sun provide one of the most accurate methods of detecting long-term changes in the solar diameter. These observations are spread over some 300 yr. Due to the particular geometry of the orbits of the Earth and Mercury, transits occur only in May or November, and there are ~14 in a century. The maximum duration of a central transit in May is ~8 h and in November it is ~6 h. Thus, if the instants at which Mercury seemed to touch the rim of the Sun were timed to a precision of 1 s, the resolution obtained for the solar diameter would be ~0.1 arcs. However, due to the observational difficulty of discerning when Mercury first touches the limb of the Sun, the standard deviation of the observations of each transit are typically in the range 0.5–1.0 arc s. It is also necessary to restrict observations to timings of the first and last instants (contacts 2 and 3) at which Mercury appears completely inside the limb of the Sun; these internal contacts are more definite than the external ones.

Over 2,000 timings of the internal contacts of 30 transits of Mercury spread over the past 250 yr have been used in this analysis. The observations of these transits have been collected by Morrison and Ward<sup>12,13</sup> mainly to determine fluctuations in the Earth's rate of rotation and the relativistic advance in the perihelion of Mercury's orbit. When allowance has been made for these and other orbital parameters (see solution 2, Table III of ref. 13), the angular separation between the centres of the Sun and Mercury, calculated from the observed times of internal contact, should be equal to the difference of their semi-diameters.

The residual angular separation for each observation has been calculated using values of 959.63 and 3.37 arcs for the semi-diameters of the Sun and Mercury at unit distance. The means and standard deviations of the distributions of the residuals for 30 of the transits in the period 1723 to 1973 are plotted in Fig. 3 where they are compared with the meridian circle trend claimed by Eddy and Boornazian<sup>2</sup>. To make this comparison we have subtracted 1.55 arcs from the meridian circle observations, this being the generally accepted value used to account for the somewhat arbitrary effect of irradiation<sup>14</sup>.

The results from the transits shown in Fig. 3 are at variance with the change in the semi-diameter claimed by Eddy and Boornazian between 1836 and 1953 and rule out any extrapolation of this trend to other epochs. A linear regression analysis of the Mercury transits produces a secular trend of  $-0.14 \pm 0.08$  arcs per century in the solar semi-diameter, broadly agreeing with Shapiro<sup>15</sup>, who reported a decrease of less

Fig. 4 Spectrum of the apparent changes in the semi-diameter deduced from transits of Mercury shown in Fig. 3.

Fig. 5 An enlargement of a frame from J. H. Mathers' 16-mm cine film of the solar eclipse of 20 May 1966 taken on the island of Lesbos in Greece. The jagged outline of the Moon, exaggerated by a factor of 60, is shown superimposed on the frame. Baily's beads can be seen in the lunar depressions.

than 0.15 arcs per century with >90% confidence from a smaller set of Mercury transit observations.

We have also examined the data for possible periodic changes using a least-squares frequency analysis. Sine curves were fitted to the data by least squares and the percentage reduction in the sum of the squares is shown in Fig. 4. There are significant peaks at 80 yr and 19.6 yr. Removal of one of these sinusoids from the data reduces the other to the level of the noise. One is therefore the alias of the other, and is caused by the particular spacing of the transits. Because the 80-yr peak is the higher of the two, it is more likely to be the basic causal period, but we cannot be certain of this<sup>16</sup>.

The amplitude, phase and standard errors of the 80-yr sinusoid were found to be given by:

$$\begin{aligned} \text{change in semi-diameter (arc 2)} = \\ 0.24(\pm 0.08) \sin 2\pi[(t-1700)/80 + 0.43(\pm 0.04)] \end{aligned}$$

where  $t$  is the year of the observation.

## Total solar eclipses

The observed durations of total solar eclipses, typically a few minutes, present an alternative method of detecting possible long-term changes in the solar diameter. The timing of such a duration to a precision of 1 s would give a measure of the Sun's semi-diameter to an accuracy of ~0.2 arcs assuming that the profile of the Moon were known accurately. In practice observations need to be restricted to the timing of the interval between the disappearance of the last and the reappearance of the first beads of light, which are seen at the irregular edge of the Moon at the beginning and end of total eclipses.

The edge of the solar photosphere is extremely well defined and eclipse observers have shown that, until the last bead of light shining down one of the depressions on the lunar limb has disappeared, then totality has not yet started. Perhaps the best test is the internal consistency of timings of totality by independent observers, which is typically a few seconds of time. Although the absolute times of the contacts might well be in error, only the duration of totality is important in determining the diameter and even in the early eighteenth century it was possible to time such durations to within a second or two by counting the beats of a pendulum clock.

In our investigation of solar eclipses, we have used visual observations of the durations of the total eclipses of 1715, 1842, 1851, 1878, 1900 and 1925. We have also analysed photographs of the eclipse of 1966, which was intermediate between total and annular.

After Halley<sup>17</sup> had carefully organized timings of the 1715 eclipse, there are no comparable timings until 1842. From then until 1925, eclipses were chosen that were reasonably uniformly spaced in time and also the individual reports are fairly easily accessible. References are too numerous to cite here. After 1925 only scattered timings are available and we have accordingly ended our investigation of such material at that date.

In analysing these eclipse observations we have adopted the values of 959.63 and 932.58 arc s for the solar and lunar semi-diameters at mean distance and applied lunar limb profile corrections for each individual observation<sup>18</sup>, the errors of which are unlikely to exceed 0.2 arc s at any point. Many of the observations were made quite close to the central line of the shadow path, where the duration was greatest. We have rejected all observations for which the duration was less than ~1 min because the location would be very close to either of the edges of the zone of totality. In these circumstances it becomes difficult to identify exactly which depressions on the Moon's limb permit the appearance of the last and first beads of light. The results of this analysis are plotted in Fig. 3 alongside the Mercury transit data. For each eclipse, the mean correction to the Sun's semi-diameter and the standard deviation of the individual observations is shown.

During the eclipse of 20 May 1966, Mathers took a 16-mm cine film of the central phase from the island of Lesbos in Greece. From this point in the path of the eclipse, the calculated solar semi-diameter was only 0.07 arc s greater than that of the Moon. Mathers positioned himself almost exactly on the central line and at the time of maximum eclipse the Sun was seen to be

reduced to a broken circle of light composed of ~50 individual beads (see Fig. 5). On the eight frames nearest to the time of greatest phase we have been able to identify each bead of light with a depression of the lunar limb as plotted by Duncombe<sup>18</sup>. From a consideration of the visibility of the various beads, we deduce a correction of  $-0.22 \pm 0.20$  arc s to the adopted semi-diameter of the Sun. This provides a valuable additional point on Fig. 3.

Figure 3 shows that, in general, the accuracy of the eclipse results is similar to that of the Mercury transit data. If we include the eclipses with the transits in a linear regression analysis, the secular trend in the semi-diameter reduces to  $-0.08 \pm 0.07$  arc s per century. This corresponds to a change of  $-0.008 \pm 0.007\%$  per century, well over an order of magnitude smaller than the rate claimed by Eddy and Boornazian.

## Conclusion

The combined data sets of the Mercury transit and total solar eclipse observations, which cover a much longer time span than the material used by Eddy and Boornazian, demonstrate that there has been no detectable secular change in the solar diameter over the past 250 yr or so. However, there is some evidence that periodic changes of about 0.02% on a time scale of 80 yr may have occurred. The findings of Eddy and Boornazian are the result of instrumental and observational defects rather than real changes, hence the problem of the missing solar neutrinos still remains.

We thank Mr J. H. Mathers for use of his unique eclipse film. *Note added in proof:* In a recent preprint by Dunham *et al.*<sup>19</sup> they deduce, from observations made near the limits of the total eclipses of 1715 and 1976–79, that the Sun's semi-diameter decreased by  $0.34 \pm 0.2$  arc s in this interval. Their result depends critically on the interpretation put on the only observation made near the northern limit of the 1715 eclipse.

# Angiogenesis *in vitro*

Judah Folkman\* & Christian Haudenschild

The Department of Surgery, Children's Hospital Medical Center and The Harvard Medical School and The Mallory Institute of Pathology, Boston, Massachusetts 02115

*Cloned capillary endothelial cells, cultured in tumour-conditioned medium, form capillary tubes. By light and electron microscopy these tubes resemble capillaries in vivo. This first demonstration of angiogenesis in vitro: (1) shows that all the information necessary to develop an entire capillary network in vitro is expressed by one cell type; (2) suggests a mechanism for lumen formation; and (3) offers a possibility of distinguishing between direct and indirect angiogenesis factors.*

MOST, if not all, solid tumours are capable of continuously inducing the proliferation of new capillary blood vessels from the host vascular bed. There is accumulating evidence that this property, angiogenesis, is important for the progressive growth of solid tumours<sup>1–3</sup>. Previous studies have described the growth and regression of new capillaries *in vivo*<sup>4,5</sup> but there is little understanding of how a capillary grows. It is not known how a lumen develops in a capillary sprout, how branches arise, or how

anastomoses are made between one capillary loop and another. Until now, angiogenesis could be studied only in animal models<sup>6,7</sup> or in the chick embryo<sup>8</sup>. Lack of an *in vitro* model has made the investigation of angiogenesis as difficult as the study of blood coagulation would be without *in vitro* methods.

In a previous report, bovine capillary endothelial cells were cloned, and bovine and human capillary endothelial cells were carried in long-term culture<sup>9</sup>. We show here that in appropriate conditions, these capillary endothelial cells will form tubular networks *in vitro* which are almost identical, by light and electron microscopy, to capillary vascular beds *in vivo*.

\* Present address: Children's Hospital Medical Center, 300 Longwood Avenue, Boston, Massachusetts 02115.

**Fig. 1** Human capillary endothelial cells forming 'capillary' tubes (phase contrast). *a*, A cylindrical 'keyhole' vacuole (arrow) is the first evidence of tube formation. Capillary endothelial cells from Sertoli-Leydig ovarian tumour in a 16-yr-old girl. Third passage.  $\times 115$ . *b*, Same field 3 days later showing tubes that traverse the entire length of some cells, and connect with tubes of neighbouring cells.  $\times 115$ . *c*, Network of tubes formed by capillary endothelial cells from human foreskin. Tubes began to form 1 month after the primary cells were plated.  $\times 115$ . *d*, The junction of the capillary tube of one cell with another (arrow). String-like material within the lumen ('mandril') traverses the anastomosis between the two cells.  $\times 230$ . Capillary endothelial cells were isolated as described elsewhere<sup>9</sup> except that 0.75% collagenase (Worthington type II) with 0.5% bovine serum albumin (BSA) was used for digestion of tissue. Human capillary endothelial cells were grown in tumour-conditioned medium<sup>9</sup> mixed 1:1 with aortic-conditioned medium, 15% human serum and endothelial cell growth supplement (ECGS)  $5.4 \text{ mg ml}^{-1}$  (Collaborative Research). Aortic-conditioned medium was obtained from cloned bovine aortic endothelial cells grown to confluence in T-75 flasks. Dulbecco's minimal essential medium (MEM) with 10% calf serum was changed every 48 h, centrifuged (2,000 r.p.m. for 10 min), passed through a Millipore filter ( $0.22 \mu\text{m}$ ), and stored at  $-30^\circ\text{C}$ . It was thawed and centrifuged immediately before use (A growth factor has been derived from aortic endothelial cells by Gajdusek *et al.*<sup>11</sup>). Human serum was heat-inactivated at  $56^\circ\text{C}$  for 30 min before use. It was convenient to make up the media before use in 50-ml polyethylene tubes (35 ml tumour-conditioned medium, 35 ml aortic-conditioned medium, 11.5 ml human serum and 15 mg ECGS). Unused media were stored at  $4^\circ\text{C}$  for a few days. Cultures were re-fed every 48 h. Bovine capillary cells will form capillaries optimally in a mixture of 60 ml tumour-conditioned medium + 30 ml aortic-conditioned medium + 10% calf serum and 15 mg ECGS. Occasionally bovine cells will form capillaries in tumour-conditioned medium mixed 1:1 with alpha MEM or with Dulbecco's MEM with 10% calf serum (especially late passage cells). Both bovine and human cells survive freezing in dimethyl sulphoxide (DMSO) and will form capillaries after thawing. Bovine cells have been carried in culture for up to 9 months and human cells for up to 5 months. During early passage, human capillary cells must pass at high density. When Falcon (3001) plates were used (for easier weeding of non-endothelial cells<sup>9</sup>) the capillary cells were plated into a glass cloning ring (6 mm i.d.) placed in the centre of the dish.

**Fig. 2** Ring formation by single capillary endothelial cells (phase contrast). Human foreskin capillary endothelial cells without any neighbours, but stimulated by tumour-conditioned medium, seem unable to form a tube in three dimensions. Instead, they move cytoplasmic extensions along the bottom of the culture dish, until the tips of these extensions join to form a flat, two-dimensional 'ring'. *a*, *b* and *c* show different stages of this process.  $\times 230$ .

### Isolation and culture of capillary endothelial cells

Capillary segments were isolated from bovine adrenal cortex, human foreskin, human spleen, an ovarian tumour, a neuroblastoma and a rhabdomyoma of the heart as described elsewhere<sup>9</sup> (except for the modifications described in Fig. 1 legend). The amount of starting tissue need not be more than 0.1–0.5 g. Experience has shown that even a small tumour biopsy yields capillary segments in culture provided the biopsy is taken from the vascular, non-necrotic portion of the tumour. The capillary segments were cultured in tumour-conditioned medium on gelatin-coated plates<sup>9</sup>. The bovine cells were cloned, whereas endothelial cells from other tissues, also derived from a single capillary segment (2–4 capillary endothelial cells), were not cloned.

The evidence that these cultured cells are capillary endothelial cells, detailed elsewhere<sup>9,10</sup>, is as follows: (1) each culture is initiated from one capillary segment of ~2–4 capillary endothelial cells. With experience, it is possible to distinguish capillary segments from arterioles or venules. (2) The capillary endothelial cells of different organs from the same animal and from different species seem to be almost identical by phase-microscopy. (3) Both human and bovine capillary endothelial cells contain factor VIII antigens<sup>9</sup>. (4) Cultured capillary endothelial cells have a similar ultrastructure to the capillary endothelial cells of their organ of origin: human cells contain Weibel-Palade bodies—bovine cells do not. (5) Both human and bovine capillary endothelial cells form 'rings' when they are in sparse culture (Fig. 2). (6) Early passage bovine capillary endothelial cells, and human capillary endothelial cells at any passage

require conditioned medium, and grow best in tumour-conditioned medium. However, endothelial cells from aorta and umbilical vein do not require conditioned medium for growth<sup>9</sup>. (7) Capillary endothelial cells increase their rate of migration in a dose-dependent manner when increasing concentrations of tumour-conditioned medium or tumour-derived factors are added<sup>10</sup>. In contrast, the migration of aortic endothelium is not affected by tumour-conditioned medium. (8) Capillary endothelial cells have a special matrix requirement (for example, gelatin<sup>9</sup> or collagen<sup>11</sup>) for their survival.

### Development of capillary tubes *in vitro* and the origin of branches

When the endothelial cells of a single human capillary are allowed to proliferate, they form a small colony which enlarges gradually. When the colony reaches 3–5 mm, the centre approaches confluence. In ~50% of the cultures, capillary tubes begin to form in the middle zone of the colony, between the deeply confluent centre and the sub-confluent periphery. In

primary cultures of most human and bovine capillary cells, the earliest appearance of tubes is 20 days and the latest, 40 days. Capillary endothelial cells from a rhabdomyoma formed tubes 10 days after the primary culture was started. However, once tubes have formed in the primary culture, they appear earlier in subsequent passages. In the fourth passage, tubes developed in 5–10 days.

The first evidence of tube formation is the appearance (by phase contrast) of a cylindrical vacuole within an endothelial cell, which resembles a 'keyhole' (Fig. 1a). After 48 h, contiguous cells develop similar vacuoles which form a long tube connecting one cell to another (Fig. 1b). These tubes do not arise from cleavage planes between cells, but in fact traverse the cytoplasm, or the nucleus, so that the nucleus sometimes seems to be split into two parts (Fig. 1d). Electron micrographs taken at these locations always show a single nucleus which has a portion close to the lumen deformed into a thin plate positioned either at the bottom or the roof of the tube. Branches begin to appear after four or five cells have become connected, and within 5–10 days an entire network of tubes replaces the dense regions of the colony (Fig. 1c).

**Fig. 3** Organization of a second layer of capillary tubes on the dorsal surface of the original monolayer of capillary endothelial cells (phase contrast). *a*, A network of tubes began to form in the original monolayer of these 11th-passage bovine capillary endothelial cells, after 2 weeks in the same plate. A branch that was directed out of the plane of the substratum led to the formation of a second layer of tubes. This photograph shows only the second layer in focus. The first cell layer (lying directly on the gelatin) is out of focus.  $\times 115$ . *b*, Branches formed *in vitro* by capillary endothelial cells derived from human foreskin. Note the position of the endothelial cell (arrow) that lies at the intersection of two limbs. Inset shows another branch bridged by the endothelial cell from which the branch was formed. These tubes formed in a second layer of capillary endothelial cells after they had been plated into the microwells of a gelatinized Cuprak dish. Monolayers formed in the wells that contained more than one cell. When tubes appeared in these monolayers, many branches were directed out of the plane of the substratum, presumably because of the curvature of the wells. The first layer is not visible here because it is out of focus. *c*, A capillary tube, 7.5 mm long, that grew *in vitro* from fourth-passage capillary endothelial cells from human foreskin.

A branch in the tubular network always originates within a single cell. Before a branch appears, the cylindrical vacuole within a cell forms a 'Y' or a 'T', each arm of which then aligns with the vacuole of another cell. An entire capillary network develops in this way. After a branch has matured, the original endothelial cell can usually be found at the intersection of three tubes (Fig. 3b). Occasionally, a branch will be directed out of the plane of the substratum—then a second layer of capillaries organizes on the dorsal surface of the cells that were originally plated. This three-dimensional growth results in a capillary network of multiple layers (Fig. 3a, c).

### Remodelling and regression of capillary tubes

Time-lapse, phase contrast pictures (2 frames per min) taken continuously for 1 week, showed that established tubes undergo remodelling. New branches appear and others are contracted into the parent vessel within a period as short as 12 h. Once a tube has formed by the alignment of 5–10 endothelial cells, it presents a thin, phase-dense lining. The endothelial cells that embrace it also migrate along the tube and out to the tips of its branches. Tumour-conditioned medium has been shown to cause a 500% increase in migration of capillary endothelial cells *in vitro*<sup>10</sup>. Remodelling seems to be carried out primarily by migratory activity of capillary endothelial cells and not by mitosis. Furthermore, when cultures were incubated with <sup>3</sup>H-thymidine ( $4 \mu\text{Ci ml}^{-1}$  for 48 h), endothelial cells lining the tubes were not labelled, but those at the periphery of the colony were.

When the cells in a capillary network were trypsinized and re-plated, new capillary tubes formed. There was no obvious difference between the capillary networks formed by capillary endothelial cells isolated from normal or malignant human tissue.

### Ultrastructure of capillary tube formation

Transmission electron micrographs taken perpendicular and parallel to the plane of the culture dish prove that these aligned, phase-optically transparent structures are continuous lumina bordered by cell cytoplasm and membranes (plasmalemma), and that they form a network of tubes (Fig. 4a). The origin of a tube seems to be a true vacuole surrounded by one uninterrupted membrane (Fig. 4b). Later, the vacuole seems to become an extracellular tube surrounded by an extremely thin wall of cytoplasm of the endothelial cell. The tubular wall of one cell will connect to the tubular wall of another cell (Fig. 4c, d). Although we have been unable to observe the exact transition from an intracellular vacuole of one cell to an intercellular tube girdled by several cells, we have seen intermediate stages. For example, at one stage, the initially intracellular vacuole opens to form two cytoplasmic sheets (Fig. 5a) which are capable of joining with similar cytoplasmic extensions of a neighbouring cell, or with themselves (Fig. 5b). At these connections the structure resembles a junctional complex. (However, freeze-fracture and other studies to characterize these junctions formed *in vitro*, remain to be done).

Early in their development, the tubes are filled with a partially fibrillar, partially membranous and amorphous material of undetermined nature that apparently originates from the endothelial cells (Fig. 5c). In some areas, this material resembles basement membrane, and is also found outside the lumen in direct contact with the gelatin substratum. This material may serve as a guide or 'mandril' for the alignment of tubes from cell to cell. Later the material apparently dissolves, or is cleared from the lumen in some other way (Fig. 5a), because the tubes become hollow as the capillary network matures (Fig. 5d).

To control for the possibility that the tumour-conditioned medium and the gelatin-coated plates might induce tube

**Fig. 4** Transmission electron micrographs of capillary formation. *a*, Micrograph taken in a plane perpendicular to that of the culture dish, showing the formation of a tube by human capillary endothelium. Note the amorphous and fibrillar material (M) within the lumen (L), the Weibel-Palade body (arrow), some myelinated figures (F) and the junction between the two cells (arrowheads). Insert shows higher magnification of Weibel-Palade body from another tube-forming human capillary endothelial cell. *b*, Earliest phase of tube formation within one cultured capillary endothelial cell derived from bovine adrenal. The micrograph is taken in a plane perpendicular to the culture dish and demonstrates the thin cytoplasmic plate which covers the lumen (L) and which shows structures resembling fenestrations (arrow). Note the intraluminal material (M) and the pinocytotic vesicles (V). *c*, Thin cytoplasmic plates surround the lumen of a tube formed *in vitro* by capillary endothelial cells derived from human foreskin. The intraluminal material (M) is disappearing. Micrograph taken in a plane perpendicular to the culture dish. *d*, Junctional complex formed *in vitro* by two capillary endothelial cells derived from an ovarian (Sertoli-Leydig) tumour. The lumen (L) is empty. Micrograph taken in a plane perpendicular to the dish.

**Fig. 5** Transmission electron micrographs of capillary formation. *a*, Section (perpendicular to the plane of the culture dish) of a human capillary endothelial cell showing two cytoplasmic extensions at the open end of a tube partially filled with extracellular material (arrow). *b*, Human capillary endothelial cell (cross-section perpendicular to the plane of the dish). A cytoplasmic extension forms a connection resembling a junctional complex (arrow) with another cytoplasmic extension from the same cell. *c*, Micrograph taken parallel to the plane of the culture dish, showing lumen (L) beginning to form within one capillary endothelial cell derived from human foreskin. Note the fibrillar nature of the intraluminal material (M) appearing like a 'mandril' within the lumen. N, nucleus. *d*, Lumen formation by human capillary cells derived from an ovarian tumour. Note the increased number of pinocytotic vesicles in the vicinity of the sparse material (M) remaining in the lumen (L).

formation by other cells, the following non-capillary cells were cultured in the same conditions that caused tube formation by human and bovine capillary endothelial cells—human foreskin fibroblasts obtained during the isolation of endothelial cells from foreskin were cultured for 4 months. Primary cultures of human kidney epithelium and umbilical vein endothelium were maintained for 4 months and human chondrocytes for 2 months. Also, WI-38 cells, BALB/c 3T3 fibroblasts, MDCK canine kidney cells and bovine aortic endothelial cells were cultured for up to 4 months. No tubes formed in any of these cultures.

## Discussion

Our experiments show that all the information necessary to construct a 'capillary' tube, make branches and assemble an entire 'capillary' network *in vitro* can be expressed by a single cell type, the capillary endothelial cell. Other cell types are unnecessary. Therefore, mast cells and pericytes so frequently associated with capillaries *in vivo*, may have functions other than the formation and remodelling of the lumen. The unexpected finding is that cultured cells can be induced to mould into a tissue by themselves building a complex three-dimensional matrix. A further implication is that blood flow and hydrostatic pressure are not required for the organization of a vascular bed.

A general mechanism of microvascular lumen formation is suggested by the formation of an autolytic vacuole within a capillary endothelial cell, the conversion of this vacuole to a tube, the connection of one tube to another, the girdling of the tube by capillary endothelial cells that form special junctions with themselves and with each other and the ability of these cells to glide along the tube once it has formed. If these *in vitro*

observations are a valid model for growing capillaries *in vivo*, our understanding of how capillaries regenerate in wounds, proliferate at the edge of a tumour or arise from blood islands in the embryo may be enhanced.

We do not know why capillaries take so long to appear in primary cultures. One possibility is that gelatin is not the optimum substratum and the cultured capillary endothelial cells must lay down their own matrix<sup>12,13</sup>. In addition, selection may be occurring, because capillary tubes arise earlier after passage of the endothelial cells. It is highly probable that the culture medium is not optimal. The medium used in this study was found empirically after several years of failure to grow capillary endothelium. Once we observed the first tube formation, the composition of the medium was not varied. The nature of the contents of the early vacuoles, the fibrils within the 'mandril', and the mechanisms of the removal of the material from within the tubes are unknown.

These experiments do not imply that only capillary endothelial cells are the source of new capillaries. We have limited our primary cultures to capillary segments. It is well known, however, that *in vivo* new capillaries arise from venules as well as from other capillaries.

This is the first report of angiogenesis *in vitro*. Because a variety of angiogenesis factors have been reported, based on *in vivo* assays<sup>8,14-20</sup>, it will become critical to be able to distinguish between an indirect and a direct angiogenesis factor. By indirect, we mean compounds (for example formic acid and silica) that have in common the ability to attract macrophages or other white cells which might subsequently secrete a direct angiogenesis factor<sup>18,19</sup>. An indirect angiogenesis factor would be

unable to induce capillary formation *in vitro*, where only capillary endothelial cells were present. By contrast, a direct angiogenesis factor should be capable of inducing angiogenesis *in vivo* or *in vitro* independently of other cell types. As yet there is no way to make this distinction. In the future, capillary endothelial cell cultures may be used to discriminate between indirect and direct angiogenesis factors. Furthermore, this approach may be used to screen for angiogenesis inhibitors.

A better understanding of angiogenesis in general, and tumour angiogenesis in particular, will be achieved if the various components of this phenomenon can be studied *in vitro*. At least one new concept is immediately apparent. If capillary endothelial cells have the capacity to generate a whole capillary

network (in the presence of tumour-conditioned medium) then the function of a tumour angiogenesis factor may be to supply instructions for 'start' and for 'direction' of capillary growth.

We thank Drs R. Cotran, N. LeDouran, G. Majno, A. Pardee and R. Ross for reviewing the manuscript and for helpful discussion and comments, Dr Bruce Zetter for many valuable discussions, Mrs C. Butterfield, Ms N. Connell and Mr A. Wallstrom for technical assistance, Ms Jane Dittrich and Mr Carl Cobb for editorial assistance and Mrs Pauline Breen for typing the manuscript. This work was supported by NCI grant R01-CA14019, grant R01-HL23567 from the National Heart, Lung and Blood Institute, and by a grant to Harvard University from the Monsanto Company.

# Chloroplast gene sequence for the large subunit of ribulose biphosphatocarboxylase of maize

Lee McIntosh, Carsten Poulsen & Lawrence Bogorad

The Biological Laboratories, Harvard University, Cambridge, Massachusetts 02138

*The chloroplast gene coding for the large subunit of ribulose 1,5-biphosphatocarboxylase in Zea mays has been sequenced. It contains neither a 'classical' prokaryotic promoter sequence nor its proposed eukaryotic counterpart but does have a typical prokaryotic ribosome binding site close to the site at which translation is initiated. Almost all possible codons occur and are translated by the 'universal code' rather than by the variation of it found in mitochondria.*

THE enzyme ribulose biphosphatocarboxylase (RuBPCase) fixes CO<sub>2</sub> in plants and is the most abundant soluble leaf protein; it is also thought to be the most abundant protein on earth<sup>1</sup>. It is an aggregate of eight identical 12,000–14,000 molecular weight (MW) 'small' subunits together with eight identical 'large' subunits (LS) of 50,000–55,000 MW (ref. 2). The small subunit of RuBPCase is inherited biparentally in *Nicotiana* and thus appears to be coded for by a nuclear gene<sup>3</sup> which, in peas, is found among the population of unique or low copy sequences of the nuclear genome<sup>4</sup>. The large subunit, however, is encoded by chloroplast DNA for not only is it inherited maternally in *Nicotiana*<sup>5</sup> but it can also be physically mapped on chloroplast DNA in *Zea mays*<sup>6–8</sup> and in *Chlamydomonas reinhardtii*<sup>9</sup>. This distribution of the genes for the two subunits of RuBPCase between the nuclear and chloroplast genomes is an example of the widespread phenomenon of the dispersal of genes for the components of multimeric proteins of subcellular organelles<sup>10</sup>.

We report here the complete DNA sequence of the gene for the LS of *Z. mays* RuBPCase contained in a fragment of the chloroplast genome that has been cloned in *Escherichia coli*<sup>6–8</sup> and mapped on the cloned fragment<sup>7,8</sup>. The transcribed portion of the DNA sequence has some features in common with genes of other groups of organisms but overall is unique. The codons used for translation of LS mRNA include most of those possible, which has led us to consider the kinds of tRNA genes that may be found in the maize chloroplast chromosome. Furthermore, the amino acid sequence deduced from the DNA sequence has been compared and aligned with amino acid sequences obtained

earlier for some cyanogen bromide (CNBr) fragments of barley LS<sup>11</sup> and with sequences of tryptic peptides of the spinach enzyme, believed to be in or near the catalytic sites<sup>12</sup>. Stretches of the deduced amino acid sequence of maize LS are remarkably similar to the known amino acid sequences in the barley and spinach polypeptides, with the putative catalytic sites widely separated along the polypeptide.

## Features of DNA sequence for LS RuBPCase mRNA

A physical map of the maize chloroplast DNA fragment that includes the structural gene for the LS of RuBPCase is shown in Fig. 1 together with the strategy used for sequencing the region complementary to the LS mRNA. The nucleotide sequence is shown in Fig. 2.

The 5' terminus of LS mRNA was previously estimated to be complementary to the DNA for about 40 nucleotides upstream from a mapped *EcoRI* restriction site<sup>8</sup> (nucleotide –34 to –29 in Fig. 2). We have now placed the terminus more precisely using a modification<sup>13</sup> of the Berk–Sharp technique<sup>14</sup>. The 5' terminus of the transcript was previously mapped within a 196-base pair *EcoRI* fragment that is part of a larger 480-base pair *HinfI* fragment (Fig. 1). This fragment was isolated and labelled with <sup>32</sup>P at its 5' ends by polynucleotide kinase<sup>15</sup> and then digested with *HincII* endonuclease. The resulting radioactive 443-base pair *HinfI/HincII* fragment was purified by polyacrylamide gel electrophoresis and used for DNA:RNA hybridization and DNA sequencing (Fig. 3).

The radioactive segment recovered from the hybrid should represent the DNA protected from  $S_1$ -nuclease digestion by hybridization with LS mRNA. Determination of its length should establish the precise beginning of the LS transcript. Protected fragments of 219, 220, 224 and 225 bases were detected as a set of two bands. This places the 5' end of the LS mRNA 59 to 63 nucleotides from the start of the codon for the N-terminal methionine residue (nucleotide 1 in Fig. 2). Removal of a 3'-terminal phosphate by the  $S_1$  nuclease increases the electrophoretic mobility of the fragment by about 1/2 base in relation to the sequence ladder<sup>13</sup>.

Five nucleotides upstream from the N-terminal methionine codon on the LS mRNA is the sequence 5'-GGAGG-3' that is complementary to a sequence at the 3' terminus of maize chloroplast 16S rRNA<sup>16</sup>. A sequence identical with the latter is found at the 3' terminus of 16S rRNA in *E. coli* and a complementary sequence is generally found on bacterial mRNAs, about three to seven nucleotides upstream from the initiator codon. The suggestion by Shine and Dalgarno<sup>17</sup> that this complementary mRNA sequence is a translation signal was later confirmed by identification of hybrids between mRNA and sequences at the 3' terminus of 16S rRNA<sup>18</sup>. The entire 'Shine and Dalgarno' nine-nucleotide sequence of *E. coli* 16S rRNA is present in maize chloroplast 16S rRNA but only seven of the nine nucleotides at positions 5-13 upstream from the initiator codon on the LS mRNA are complementary to the maize chloroplast 16S rRNA Shine-Dalgarno sequence (Fig. 2). Another partially complementary sequence has been detected on a different maize chloroplast DNA fragment upstream of a putative translation start site for an unidentified polypeptide. (Z. Schwarz, A. Steinmetz and L. Bogorad, unpublished). Partially complementary sequences have also been seen in the *cro* gene (5'-A-A-G-G-A-G-G-3'), the *O* gene (5'-A-G-G-A-G-3') and in the *CII* gene (5'-A-A-G-G-A-3') of  $\lambda$  phage<sup>19</sup>.

### Amino acid sequence of maize LS RuBPCase

The amino acid sequence deduced from the nucleotide sequence of the structural region of the LS gene is shown in Fig. 2. The polypeptide comprises 475 amino acid residues and has a molecular weight of 52,682. This number of residues is lower than previously estimated from electrophoretic and amino acid analyses of LS of RuBPCase from species other than maize.<sup>20</sup>

The availability of the DNA sequence for the maize LS RuBPCase gene has permitted the alignment of amino acid sequences totalling 244 residues known for fragments of the barley and spinach LS polypeptides<sup>11,12</sup> with the predicted maize LS sequence (Fig. 2). There are few differences. Seven positions in the maize sequences have amino acid replacements due to single nucleotide substitutions and five of these (positions 36,

43, 282, 394 and 460) must be considered neutral replacements. The proline residues at positions 46 and 415 in the barley LS primary structure are replaced by leucine and histidine respectively. The application of methods for secondary-structure prediction<sup>21</sup> to these domains in the sequences suggest that they are not likely to have any drastic effect on secondary structure. The eighth difference, at amino acid residue 215, may be the result of an error in identification of that residue in the barley polypeptide.

Compared with the barley polypeptide<sup>20</sup>, the maize LS mRNA seems to contain a sequence for 14 amino acid residues that extends beyond the N-terminus of the barley LS sequence. This difference could be due to variation in the DNA sequences, but it seems more likely that the difference is an artefact. After SDS polyacrylamide gel electrophoresis of fragments produced by CNBr-cleavage of the large subunits from maize and from rapidly isolated barley RuBPCase, we found N-terminal fragments of identical size (MW 14,000–15,000, data not shown). The N-terminal alanine, which has previously been reported for the LS of barley<sup>11</sup>, was not found among the CNBr-fragments of either maize or barley. The N-terminal amino acid could not be identified for intact maize or barley LS polypeptides, which suggests that these are blocked, possibly by N-formyl-methionine. N-terminal blocking has now been observed for large subunits from a number of species<sup>11</sup>. It is possible that the 14 N-terminal residues of the barley LS are removed by an endo-protease present in the barley leaf extracts during the slower large-scale preparations of the enzyme<sup>11</sup>.

The amino acid sequences of spinach LS that have been proposed to be in or near the catalytic site of RuBPCase<sup>12</sup> are widely separated along the maize polypeptide, corresponding to positions 166-178, 321-340 and 450-462, and are well conserved. The only exceptions are neutral replacements at positions 330 and 460. Note that nine histidines are clustered among residues 268-327 and that this is just on the N-terminal side of one of the proposed catalytic site sequences. Four of these histidines are found in two His-Ile-His sequences (292-294 and 325-327). Whether any of the clustered imidazole groups are used for chelation of  $Mg^{2+}$ , which is required for enzyme activity, is not known. Note also that many lysine, arginine and cysteine residues are in the middle of the sequence and close to the C-terminus. Some side chains of these residues are thought to have important roles in binding to, or acting on, the substrates<sup>12,21,22</sup>. The positions in which they have been found might be close to the three proposed catalytic site sequences.

The complete amino acid sequence deduced for the maize LS polypeptide clarifies some ambiguities in previously published data<sup>20</sup> on the amino acid sequence of the barley LS: (1) An

**Fig. 1** Fine restriction endonuclease map and the strategy followed for sequencing the maize-chloroplast DNA sequence containing the gene for LS RuBPCase. The recombinant plasmid pZmc 3711 is comprised of a 2.7-kilobase pair maize chloroplast DNA fragment bearing the LS gene<sup>7</sup> incorporated into resistance plasmid RSF 1030 (ref. 8). The double-lined region indicates the boundaries of the mature LS transcript and the solid rectangle within represents the amino acid coding part of the sequence. The sequencing strategy is indicated by the arrows which originate from specific endonuclease restriction sites that were labelled at their 5' ends with [ $\gamma$ -<sup>32</sup>P]ATP. DNA sequence determination, end labelling and electrophoresis were according to the procedures of Maxam and Gilbert.<sup>15</sup>

amino acid sequence corresponding to residues 118–113 has previously been reported as arising from the barley small subunit<sup>23</sup> but the absence of a similar sequence from the spinach small subunit<sup>24</sup> and the presence of this sequence in the maize LS primary structure indicate that it was a contaminant from the large subunit. (2) An undecapeptide corresponding to amino acid positions 310–320 of maize LS was not detected on isolation of CNBr-fragments from the barley LS although the two surrounding CNBr fragments were found<sup>20</sup>. Failure to identify this undecapeptide in the course of the work on the barley enzyme might have confused the conclusions drawn from the sequencing of the peptide fragment 298–309. Although differences at one or two positions cannot be excluded, it seems likely that the two sequences are similar in this region. (3) The size of the fragment 252–267 was earlier over-estimated<sup>20</sup> due to abnormal chromatographic behaviour and the presence of a larger contaminating peptide. (4) The extra tryptophan thought to be present in the sequence 368–383 of the LS in barley<sup>20</sup> seems to be absent. (5) The assignment of isoleucine instead of tryptophan to a position in the barley LS corresponding to residue 215 in the maize LS does not comply with the simple nucleotide substitution patterns observed for the eight replacements described above. However, phenylthiohydantoin derivatives of isoleucine and tryptophan may have been confused in the HPLC system used for their identification<sup>23</sup>. Tryptophan has been detected in the sequence 214–243 in a Trp-Arg peptide after tryptic digestion of the corresponding barley CNBr fragment<sup>20</sup>. Because no other tryptophans in this sequence can be deduced from the nucleotide sequence, tryptophan is the most likely residue at this position in the barley LS.

The major difference in the amino acid sequence seems to be that between the C-termini of the barley and maize large subunits—the barley LS showed Leu-Ala-Val-COOH as C-terminal residues. This sequence cannot be obtained from the maize LS C-terminus by nucleotide sequencing. It is possible that this discrepancy is an artefact of the same type as described for the N-terminus and further study of the barley LS gene may clarify this.

### Codon usage in the LS gene

Figure 4 shows the frequency with which amino acid codons are used in the synthesis of the LS of maize RuBPCase. All 20 amino acids are used and all codons except for three which may be used in other chloroplast genes. There is a strong bias towards having adenine and thymine bases in the third position of the codons used. In the maize LS gene 178 thymine, 145 adenine, 78 cytosine and 75 guanine bases occur in the third position of the codon. These distributions are similar to those found for codon usage in the human mitochondrial gene for cytochrome oxidase subunit II<sup>25</sup>. However, we did not find the stop codon, UGA, used for tryptophan as it is in the mRNA for cytochrome oxidase II from human<sup>25</sup> and yeast mitochondria<sup>26</sup>.

The use of almost all codons possible in the LS mRNA seems to be inconsistent with earlier results for the number of tRNA genes in maize chloroplasts. Saturation-hybridization studies conducted with maize cpDNA and chloroplast tRNAs gave an estimate of 20–26 tRNA genes on the maize chloroplast chromosome<sup>27</sup>. Similar types of hybridization experiments have given estimates of 18–25 chloroplast tRNA genes for *Euglena*<sup>28</sup> and 30–40 tRNA genes for pea<sup>29</sup>.

Recently these hybridization data have been complemented by separation of chloroplast 4S RNAs in two-dimensional gel electrophoresis and identification of the individual tRNAs by charging them using *E. coli* and chloroplast aminoacyl tRNA synthetases<sup>30,31</sup>. Maize chloroplast tRNAs separated in this manner yielded approximately 28 spots of which 25 were charged by 17 amino acids.

If, as predicted by the LS gene, almost all codons were used, a minimum of 32 tRNAs are required if the G–U wobble hypothesis is followed<sup>32</sup>. This is inconsistent with the saturation-hybridization data<sup>27</sup> but the conditions in those experiments may not have favoured hybridization of all the tRNAs. In

**Fig. 3** Localization of the 5' terminus of the LS mRNA on the coding strand of the LS gene. This experiment was carried out using a modification of the method of Berk and Sharp<sup>14</sup>. A <sup>32</sup>P 5'-terminally labelled DNA fragment was denatured and hybridized with RNA samples, digested with S<sub>1</sub> nuclease, and the length of the protected fragment was measured by polyacrylamide gel electrophoresis in 8.3 M urea. Total maize chloroplast RNA was obtained from isolated chloroplasts<sup>8</sup>. The DNA probe was a 443 base pair *HinfI/HincII* DNA fragment (see Fig. 1) with the 5' end labelled at the *HinfI* restriction endonuclease site, that is, on the coding strand of DNA for the LS gene. The *HinfI/HincII* fragment was denatured at 65 °C in flame-sealed 10-μl siliconized glass capillary pipettes. The 10-μl hybridization mixture was composed of 80% w/v deionized formamide, 0.4 M NaCl, 0.04 M PIPES (pH 6.4), 1 mM EDTA, 20–50 ng DNA probe and 30 μg of total chloroplast RNA<sup>8,14</sup>. Digestion was carried out with 20 units of S<sub>1</sub> nuclease in a total volume of 110 μl of dilution buffer (0.25 M NaCl, 0.02 M NaOAc, 1 mM ZnSO<sub>4</sub>, 20 μg ml<sup>-1</sup> freshly denatured calf thymus DNA) for 20 min at 40 °C. The S<sub>1</sub>-resistant material was precipitated with ethanol and resuspended in 80% formamide, 50 mM Tris-borate (pH 8.3), 1 mM EDTA, and electrophoresed on 6% polyacrylamide 8.3 M urea gels. Results are shown in the autoradiograph. The sample in lane a was probe DNA treated with S<sub>1</sub> nuclease in the absence of chloroplast RNA—the only DNA band seen is a residual amount of double-stranded (therefore S<sub>1</sub> nuclease resistant) probe. The DNA used in lane c was subjected to hybridization incubation without RNA. It was not treated with S<sub>1</sub> nuclease. The DNA in lane b was from the reaction mixture in which RNA was present during hybridization incubation and treatment. Two wide bands are seen representing four DNA fragments protected from digestion by hybridization with LS mRNA. Their sizes and positions in the DNA sequence were determined by comparison with the G-reaction for the original DNA fragment, shown in lane d.

**Fig. 4** Use of codons in the translation of the maize LS mRNA. All codons but three are used. The three codons not used, ACG(Thr), CGG (Arg) and AGC (Ser), may be used for other chloroplast proteins.

addition, too few tRNAs are revealed by two-dimensional separation of chargeable tRNAs<sup>31</sup>. It is possible that specific tRNAs are preferentially lost and/or degraded during isolation, that some may be present in amounts below the level of detection, or that chloroplast tRNAs may not all be chargeable with the *E. coli* tRNA aminoacyl synthetases usually used<sup>31</sup>. Another possibility is that tRNAs are superimposed on one another in two-dimensional electrophoresis. The latter has occurred in one case, where a tRNA<sup>Leu</sup> spot contains two isoacceptors (A. Steinmetz, personal communication).

There is no firm evidence that RNA is transported into higher-plant chloroplasts. It may therefore be reasonable to assume that chloroplasts contain a full complement of tRNAs, some of which have not been detected. However, it is possible that chloroplasts of some species contain only a limited set of tRNAs and use a different protein synthesizing system, or an alternative codon reading method such as the 'two out of three' system<sup>33</sup> could be used. This mechanism requires that only the first two bases be read in codon recognition and thus only 24 tRNAs be required.

## Conclusions

A number of features of transcribed and adjacent non-transcribed portions of the maize gene for LS of RuBPCase can be enumerated: (1) The two ribonucleotides at the 5' terminus of LS mRNA are most probably adenosines (AA, see Fig. 3)—other experiments (S. O. Jolly, L. McIntosh and L. Bogorad, unpublished) show that maize chloroplast DNA-dependent RNA polymerase initiates transcription *in vitro* at a position equivalent to the 5' end of the LS mRNA in the presence of the S factor described by Jolly and Bogorad<sup>34</sup>. Thus, the 5'-terminus

of LS mRNA is very likely to be at the site of initiation of transcription and is not processed. (2) The mRNA transcript carried an almost complete Shine-Dalgarno sequence a few nucleotides upstream from the translation initiation codon. Preliminary evidence (Z. Schwarz, A. Steinmetz and L. Bogorad, unpublished) indicates that at least one other mRNA in the chloroplast may carry this type of prokaryotic signal sequence. (3) It is not known whether chloroplast mRNAs are capped, as are eukaryotic and viral mRNAs<sup>35</sup>, but the LS DNA sequence shows no apparent homology to identified capping sequences<sup>36,37</sup>. Thus, unless some entirely different signal sequence is recognized by a chloroplast capping enzyme, LS mRNA is similar to prokaryotic messages in lacking a cap. (4) No DNA sequence homologous to a classical bacterial promoter<sup>38</sup> nor its presumed eukaryotic counterpart, the 'Hogness' box<sup>39</sup>, is found upstream from the transcribed portion of the maize LS gene. (5) The colinearity of LS mRNA with the DNA sequence is confirmed. (6) Almost all possible codons are used in the LS gene. (7) Analysis of the codon usage by the LS mRNA indicates that, unlike fungal<sup>26</sup> and mammalian<sup>25</sup> mitochondria, the universal genetic code is used in chloroplasts.

It is not known how many of the features listed will prove to be universal for chloroplast mRNAs although it would not be surprising if many were general. Another characteristic which may be universal is the striking conservation of amino acid sequences between the LS polypeptides of maize, barley and spinach. Only seven or eight amino acid substitutions have been detected among 228 (of 475) amino acids sequenced for LS in barley<sup>20</sup> and corresponding portions of the deduced amino acid sequence in maize. It is possible that sequence conservation of multimeric enzymes, especially those whose components are dispersed in two different genomes<sup>10</sup>, will prove to be common.

In understanding the three-dimensional structure of this polypeptide and the mechanism of its enzymatic action, it is interesting that the active site sequences are widely separated in the maize polypeptide; thus, extensive folding must be required to bring these sequences close together.

The hypothesis that chloroplasts and mitochondria evolved from prokaryotic symbionts in pro-eukaryotic cells has been well received. Evidence to support this view has been mainly the presence of 'prokaryotic features' in organelle nucleic acids and proteins and the 'retention' of presumed biochemical relics. The alternative genetic code used by mitochondria, that is, UGA coding for tryptophan<sup>25,26</sup>, and the failure to detect prokaryotic-type promoter sequences adjacent to chloroplast genes emphasize that organelles—regardless of their origin—are unique.

This research was supported in part by research grants from the USDA Competitive Research Grants Program, the NSF, and the Maria Moors Cabot Foundation of Harvard University. # Recognition sequence of bacteriophage $\Phi$ X174 gene A protein—an initiator of DNA replication

A. D. M. van Mansfeld<sup>\*†</sup>, S. A. Langeveld<sup>\*</sup>, P. D. Baas<sup>\*†</sup>, H. S. Jansz<sup>\*†</sup>,

*Gene A protein, the initiator protein of bacteriophage  $\Phi$ X174 DNA replication, cleaves synthetic single-stranded oligodeoxyribonucleotides at the same site as the corresponding sequence at the  $\Phi$ X origin. The results identify the recognition sequence within the decamer CAACTTGATA which is cleaved next to the G residue. Further requirements for cleavage of double-stranded DNA by the gene A protein are supercoiling and an A + T-rich domain adjacent to the recognition sequence.*

THE single-stranded circular  $\Phi$ X DNA replicates via a double-stranded circular intermediate, the replicative form (RF)<sup>1</sup>.  $\Phi$ X DNA replication is initiated by the introduction of a single nick in one strand, the viral strand, of the RF DNA by the virus-coded gene A protein<sup>2</sup>. *In vivo*<sup>3</sup> and *in vitro* studies<sup>4-6</sup> have shown that this nick resides at a unique site of the  $\Phi$ X RF DNA molecule and that  $\Phi$ X DNA replication starts at this nick. Therefore, the site of the gene A protein nick in  $\Phi$ X RF DNA is the origin of DNA replication. Because only two macromolecular components—the DNA and the gene A protein—are involved, the  $\Phi$ X system is particularly favourable for studying the initiator–origin interaction at the molecular level.

Previous studies from our laboratory<sup>4</sup> have shown that the purified gene A protein nicks the viral strand of  $\Phi$ X RFI DNA,

creating a 3'OH-G residue at position 4,305 of the  $\Phi$ X DNA sequence<sup>7</sup>. After nicking, the gene A protein remains covalently bound at the 5'-end of the nick<sup>4,6,8</sup>. Further studies have shown that the RFI DNAs of the bacteriophages G4, St-1, U3, G14 and  $\alpha$ 3 are also nicked by the  $\Phi$ X gene A protein<sup>9-11</sup>. Comparison of the sequences around the nick sites in  $\Phi$ X, G4 and St-1 shows that the three phages have an uninterrupted stretch of 10 nucleotides, CAACTTGATA, in common<sup>10</sup>. This suggests that the recognition site of the  $\Phi$ X gene A protein lies within this 10-nucleotide sequence.

The present study is concerned with the further elucidation of the recognition nucleotide sequence of the  $\Phi$ X gene A protein, and used synthetic oligodeoxyribonucleotides as substrates for the purified gene A protein. This approach was suggested by the

For the incubation with the A\* protein values for a were not determined.

\* 100% in parts a and b is the sum of the radioactivity present in bands 1–16 and 3–16, respectively.

† This material represents unknown minor component which is also seen in Fig. 2, lane b.

‡ This value is relatively high, because an unknown minor component which is also seen in Fig. 2, lane b, also migrates at this position.

§ Although the oligonucleotides with chain lengths 13 and 12 are also degraded by incubation with the gene A protein or the A\* protein, there is no corresponding appearance of <sup>32</sup>P-labelled tetra- and trinucleotide cleavage products. The most likely explanation for this is that during incubation with spleen phosphodiesterase, some degradation from the 3' end of the hexadecamer also occurs. This yields oligonucleotides shorter than 16 residues, all of which give rise to a <sup>32</sup>P-labelled cleavage product seven residues long.

**Fig. 1** Characterization of the synthetic hexadecamer. The synthetic hexadecamer was labelled at the 5' end with radioactive phosphate according to the protocol of Maxam and Gilbert<sup>19</sup>. [ $\gamma$ - $^{32}$ P]ATP,  $\sim 2,000$  Ci mmol<sup>-1</sup>, was from the Radiochemical Centre and T4-induced polynucleotide kinase was from Boehringer Mannheim. The labelled oligonucleotide (0.18 pmol) was partially digested with snake venom phosphodiesterase (32 pg Worthington) by incubating for 1 or 20 min at 37 °C in 10 mM Tris-HCl (pH 7.5), 1 mM EDTA, 10 mM MgCl<sub>2</sub> and 5 mM dithiothreitol (DTT) in a volume of 20  $\mu$ l. The reaction was stopped by addition of 50  $\mu$ l phenol and vigorous mixing. After separating the phenol and water phase, the water phase was extracted with ether to remove residual phenol. The water phases of the different incubations (1 min and 20 min) were mixed. Aliquots (1.25  $\mu$ l) of this mixture were applied to a cellulose-acetate strip and the radioactive products were separated by electrophoresis (1st direction) and homochromatography (2nd direction) on a PEI-cellulose thin layer using a 3% 'homomix' and visualized by autoradiography as described before<sup>15</sup>. The 5'-labelled oligonucleotide was also subjected to the chemical method for sequencing DNA devised by Maxam and Gilbert<sup>18</sup>, with modifications as described recently<sup>19</sup>. The digonucleotide was treated with alkali (the so-called A > C reaction), dimethylsulphate (G), piperidinium formate (A + G), hydrazine (C + T), and hydrazine in the presence of salt (C). To obtain a higher recovery of this short DNA fragment at the ethanol precipitations, the ethanol to water ratio was raised to 4:1 (instead of 3:1). After the modifications the cleavage reactions were performed with 1 M piperidine. The samples were then lyophilized repeatedly, dissolved in 7.5  $\mu$ l 98% formamide containing 0.05% bromophenol blue (BPB) and 0.05% xylene cyanol F (XFC) and applied onto a thin (0.45 mm) 25% polyacrylamide gel containing 50 mM Tris-borate (pH 8.35), 1 mM EDTA (TBE buffer) and 7 M urea. Electrophoresis was performed at 30 W until the XCF marker had migrated 9 cm. *a*, The autoradiograph of the radioactive products separated by electrophoresis and homochromatography. *b*, The interpretation of the autoradiograph. The capitals indicate which nucleotide causes the shift of an oligonucleotide to the next longer one. *c*, The autoradiograph of the sequencing gel, aligned with the sequence deduced from the successive bands.

finding that the gene A protein nicks single-stranded  $\Phi$ X DNA only once and at exactly the same position as  $\Phi$ X RFI DNA<sup>12</sup>.

The gene A of bacteriophage  $\Phi$ X not only codes for the gene A protein (molecular weight (MW) 55,000), but also for the A\* protein (MW 37,000) which is formed from a natural internal initiator site within gene A<sup>13</sup>. The function of the A\* protein is unknown. It does not nick  $\Phi$ X RFI DNA. However, the purified A\* protein can cleave the single-stranded viral DNA of  $\Phi$ X at many different sites<sup>12</sup>. Gene A protein and A\* protein were purified as described recently<sup>14</sup>. Both proteins were available in pure form, and therefore we also tested the action of the A\* protein on the synthetic oligonucleotides.

### Characterization of the hexadecadeoxyribonucleotide

The hexadecamer CAACTTGATATTAATA was synthesized using the phosphotriester method<sup>15,16</sup>. This sequence corresponds to nucleotides 4,299–4,314 in the  $\Phi$ X DNA sequence<sup>7</sup>. It contains the gene A protein cleavage site (at the 3' side of the G residue) in  $\Phi$ X DNA and the remarkable self-complementary sequences left (CAACTTG) and right (TATTAATA) of this site. It was thought that these self-complementary structures might have a role in the recognition between the gene A protein and the DNA.

**Fig. 2** The nicking activity of the gene A protein and A\* protein on the hexadecamer and derivatives. 5'-Labelled oligonucleotide (0.045 pmol) was incubated with gene A protein (0.9 pmol) or A\* protein (0.72 pmol) in 50 mM Tris-HCl (pH 7.5), 1 mM EDTA, 10 mM MgCl<sub>2</sub>, 5 mM DTT and 150 mM NaCl for 45 min at 37 °C in a volume of 12 µl. Then 1 µl 150 mM EDTA (pH 8.0) and 1 µl of a solution of proteinase K (Merck Darmstadt), 2 mg ml<sup>-1</sup> in 1 mM Tris-HCl (pH 7.5), 0.1 mM EDTA, preincubated for 30 min at 37 °C, were added and the incubation was continued for 30 min at 37 °C. Then 15 µl 98% formamide containing 0.05% XCF and 1 µl 1% sarkosyl (Ciba-Geigy) were added, the sample was heated for 30 s at 100 °C and applied to a 25% polyacrylamide gel in TBE buffer containing 7 M urea. Electrophoresis was carried out at 35 W until the XCF marker had migrated 9 cm. Autoradiography was performed at -20 °C. Instead of the hexadecamer, the mixture of oligonucleotides, obtained by shortening the hexadecamer from the 3' end by digestion with snake venom phosphodiesterase as described in Fig. 1 legend, was used. A third series of incubations was carried out with a mixture of oligonucleotides that had been obtained by shortening the hexadecamer from the 5' end; 150 pmol hexadecamer was incubated with 7.5 µg spleen phosphodiesterase (Boehringer Mannheim) in 20 µl 10 mM Tris-HCl (pH 7.5), 1 mM EDTA for 10 min at 37 °C. Phenol was added to stop the reaction. After vigorous mixing and separation of the phenol and water phase, the water phase was extracted with ether and the oligonucleotides were labelled at their 5' end as described in Fig. 1 legend. The oligonucleotide mixture (0.05 pmol) was used in the different incubations. Lanes a, b, c: the hexadecamer incubated without (a), with gene A protein (b) or with A\* protein (c). Lanes d, e, f: the mixture of oligonucleotides obtained after partial digestion with snake venom phosphodiesterase and incubation without (d), with gene A protein (e) or with A\* protein (f). Lanes g, h, i: the mixture of oligonucleotides obtained after partial digestion with spleen phosphodiesterase and labelling at the 5' end, followed by incubation without (g), with gene A protein (h) or with A\* protein (i).

The nucleotide sequence of the synthetic DNA was confirmed using two different methods. The DNA was labelled at the 5' end with <sup>32</sup>P and partially digested with snake venom phosphodiesterase from the 3' end. The resulting oligonucleotides were separated by the standard two-dimensional system<sup>17</sup>. From the shifts in mobility of the successive radioactive products, a nucleotide sequence can be deduced (Fig. 1a, b) which is consistent with the one expected. The 5'-labelled synthetic DNA was also subjected to the chemical method for sequencing DNA<sup>18,19</sup>. Again the sequence deduced from the successive bands in the autoradiograph (Fig. 1c) is consistent with that expected. However, from the intensities of the second slowest bands in the five lanes it can be inferred that a minor part of the hexadecamer has a deoxyguanosine instead of a deoxyadenosine as the 3'-terminal building block.

### The ΦX gene A protein and A\* protein nick the hexadecamer

The 5'-<sup>32</sup>P-labelled hexadecamer was incubated with the purified ΦX gene A protein or the A\* protein. Analysis of the reaction mixtures by polyacrylamide gel electrophoresis (Fig. 2, lanes a-c) shows that the mobility of a large portion of the labelled DNA is now present at a position corresponding to an oligonucleotide with a chain length of 7. This indicates that the gene A protein as well as the A\* protein cleave the hexadecamer at the 3' side of the G residue, that is, at the same site at which gene A protein cleaves ΦX RFI DNA<sup>4</sup> as well as ΦX single-stranded DNA<sup>12</sup>. The A\* protein also cleaves ΦX single-stranded DNA at this site although other sites are also cleaved<sup>12</sup>. Some minor products with mobilities corresponding to chain lengths between 11 and 10 and between 10 and 9 nucleotides can also be observed (Fig. 2, Table 1a). We do not know how these minor products arise nor what they represent. To obtain extensive cleavage, the same high molar ratio (10-20:1) of enzyme to substrate is required as in the reaction with ΦX RFI DNA<sup>4-6,12</sup>.

### Which part of the hexadecamer is required for cleavage by gene A protein or A\* protein?

First, it was determined which nucleotides from the 3' end of the hexadecamer are dispensable for cleavage by the gene A protein or the A\* protein. Therefore, the synthetic DNA was labelled with <sup>32</sup>P at the 5' end and partially degraded by snake venom phosphodiesterase to form a mixture of oligonucleotides ranging from 1 to 16 nucleotides in length, all having the same 5' end.

This mixture was exposed to the gene A protein or the A\* protein, respectively, and the products were analysed by polyacrylamide gel electrophoresis. The results (Fig. 2) show that a clear separation of the 16 oligonucleotides is obtained (lane d, control), and that both the gene A protein (lane e) and the A\* protein (lane f) cleave the DNAs containing 16 to 10 nucleotides whereas the DNAs containing ≤9 nucleotides remain intact. The increase of DNA containing seven nucleotides (lanes e, f) indicates that cleavage occurs at the 3' side of the G residue in all oligonucleotides which are susceptible to cleavage by the gene A protein and the A\* protein, respectively. These conclusions were confirmed by the determination of Cerenkov counts in the radioactive bands of the polyacrylamide gel (Fig. 2). As shown in Table 1a, the radioactivity of the oligonucleotides with lengths of 16 to 10 nucleotides decreases after incubation with gene A protein. The only significant increase in radioactivity is observed for the oligonucleotide containing seven nucleotides. The radioactivity of the other oligonucleotides does not differ significantly after incubation with or without gene A protein.

From the results in Fig. 2 and Table 1a, we conclude that the decamer CAACTTGATA is still cleaved, next to the G residue, by the gene A protein or the A\* protein. Cleavage no longer takes place on further degradation from the 3' end, indicating that cleavage is specified by no more than the three nucleotides ATA behind the cleavage site.

The following experiment established which nucleotides from the 5' end of the hexadecamer are dispensable for cleavage by the gene A protein or A\* protein. The synthetic DNA was degraded partially from the 5' end by incubation with spleen phosphodiesterase. In the resulting mixture the oligonucleotides have different 5' ends but the same 3' end. They were then <sup>32</sup>P-labelled at their 5' ends and incubated with gene A protein or A\* protein. The radioactive products of these reactions were analysed by electrophoresis on a polyacrylamide gel and compared with the undigested mixture of oligonucleotides

Fig. 2, lanes *g-i*). The Cerenkov radiation from the radioactive bands was determined and the relative amounts were calculated (Table 1*b*). The results show that  $^{32}\text{P}$ -labelled oligonucleotides with chain lengths of seven, six and five nucleotides are formed after incubation with the gene *A* protein or the *A\** protein (Fig. 2, lanes *g-i*). Assuming that cleavage always occurs next to the G residue, these results indicate that not only is the hexadecamer cleaved, but also the oligonucleotides which are shorter at their 5' ends by one and two nucleotides, respectively. The quantitative results (Table 1*b*) show that the oligonucleotides with 16, 15 and 14 residues are cleaved with equal efficiency by the *A\** protein. In all three cases, ~70% of the  $^{32}\text{P}$  disappears from the original position and appears at the corresponding position of the  $^{32}\text{P}$ -labelled cleavage product. However, in the reaction with the gene *A* protein, 69% of the hexadecamer disappears and is associated with the corresponding appearance of the oligonucleotide with 7 residues, whereas only 35% and 22% of the oligonucleotides with 15 and 14 residues disappear, respectively. Therefore, among the products which had been shortened from the 5' end, the hexadecamer is clearly the best substrate for the gene *A* protein. The possibility that the observed small cleavage effect on the oligonucleotides with 15 and 14 residues by the gene *A* protein is due to a slight contamination of the gene *A* protein preparation by *A\** protein has not been excluded.

The results show, however, that at least the five nucleotides ACTTG before the cleavage site, are necessary for cleavage. Together with the observation that the three nucleotides ATA after the cleavage site are indispensable, this suggests that the minimal substrate for gene *A* protein and *A\** protein is the octamer ACTTGATA.

This octamer was synthesized using the phosphotriester method<sup>15,16</sup>. It was labelled at the 5' end and the nucleotide sequence determined using the two different methods as described for the hexadecamer (Fig. 3*a-c*). The sequence deduced from both analyses is consistent with that expected: ACTTGATA. Incubation of the octamer with the gene *A* protein did not result in an altered migration of the radioactive starting material (Fig. 4*A*, lanes *c, d*). Control experiments with the hexadecamer (Fig. 4*A*, lanes *a, b*) and a mixture of the hexadecamer and the octamer (Fig. 4*A*, lanes *e, f*) clearly show that the gene *A* protein was active and cleaves the hexadecamer. Analysis after incubation of the octamer with the *A\** protein (Fig. 4*B*, lanes *c, d*) shows that the *A\** protein cleaves the octamer. The resulting product is five nucleotides long, so *A\** protein cleaves the octamer as expected, at the 3' side of the G residue. Control experiments with the hexadecamer (Fig. 4*B*, lanes *a, b*) and a mixture of the hexadecamer and the octamer (Fig. 4*B*, lanes *i, j*) show that the hexadecamer is a much better substrate for the *A\** protein than the octamer. In the mixture of

**Fig. 3** Characterization of the synthetic octamer. The synthetic octamer was labelled at the 5' end and subjected to the different sequence analyses as described for the hexadecamer in Fig. 1 legend. *a*, The autoradiograph of the radioactive products obtained by partial digestion with snake venom phosphodiesterase and separated by electrophoresis and homochromatography. *b*, The interpretation of the autoradiograph. The capitals indicate which nucleotide causes the shift of an oligonucleotide to the next longer one. *c*, The autoradiograph of the sequencing gel, aligned with the sequence deduced from the successive bands.

**Fig. 4** The nicking activity of the gene A protein and A\* protein on the octamer. 5'-Labelled octamer or hexadecamer (0.045 pmol) was incubated with gene A protein or A\* protein as described in Fig. 2 legend. The mixtures of oligonucleotides, which had been shortened from the 3' end, or the 5' end, were prepared with snake venom phosphodiesterase or spleen phosphodiesterase as described in Figs 1 and 2 legends respectively. **A**, Lanes a, b: the hexadecamer after incubation without (a) and with (b) gene A protein. Lanes c, d: the octamer after incubation without (c) and with (d) gene A protein. Lanes e, f: the mixture of the hexadecamer and the octamer after incubation without (e) and with (f) gene A protein. **B**, Lanes a, b: the hexadecamer after incubation without (a) and with (b) A\* protein. Lanes c, d: the octamer after incubation without (c) and with (d) A\* protein. Lanes e, f: the mixture of oligonucleotides after partial digestion with snake venom phosphodiesterase after incubation without (e) and with (f) A\* protein. Lanes g, h: the mixture of oligonucleotides obtained after partial digestion with spleen phosphodiesterase and labelling of the 5' end after incubation without (g) and with (h) A\* protein. Lanes i, j: the mixture of the hexadecamer and the octamer after incubation without (i) and with (j) A\* protein.

oligonucleotides obtained after partial digestion of the octamer from the 3' end with snake venom phosphodiesterase, the A\* protein did not cleave a significant amount of any of the oligonucleotides shorter than eight nucleotides (Fig. 4B, lanes e, f). The two products obtained after partial digestion with spleen phosphodiesterase and labelling of the different 5' ends show that only the octamer is cleaved, resulting in the simultaneous appearance of an oligonucleotide with a chain length of five. The heptamer is not nicked by A\* protein (Fig. 4B, lanes g, h).

## Conclusions

The gene A protein cleaves the synthetic hexadecamer CAACTTGATATTAATA at the 3' side of the G residue, at which site the corresponding sequences in  $\Phi$ X single-stranded DNA<sup>12</sup> and RFI DNA<sup>4</sup> are also cleaved. Stepwise degradation from the 3' end shows that the decamer CAACTTGATA is cleaved by the gene A protein with about equal efficiency to the hexadecamer (Fig. 2, Table 1a). However, elimination of two residues from the 5' end greatly reduces, although it does not completely prohibit, cleavage by the gene A protein (Fig. 2, Table 1b). This suggests that the actual recognition sequence of the gene A protein is shorter than the decamer, possibly the octamer sequence ACTTGATA. This possibility is not inconsistent with the result that the gene A protein does not cleave the synthetic octamer. Similar conclusions were reached from studies on the nuclease activity of the restriction endonucleases *EcoRI*<sup>20,21</sup>, *HpaII* and *MnoI*<sup>22</sup>, using short synthetic DNAs.

It is unlikely that sequences shorter than an octamer sequence can serve as the recognition site of the gene A protein. This conclusion is based on the fact that all possible sequences which have an uninterrupted stretch of seven nucleotides in common with the decamer CAACTTGATA occur in  $\Phi$ X DNA and M13 DNA. These viral, single-stranded DNAs are not cleaved at these sites<sup>12,23,24</sup> (CAACTTG, nucleotides 1,966–1,972 in  $\Phi$ X DNA<sup>7</sup>; AACTTGA, nucleotides 2,492–2,498 and 5,695–5,701 in M13 DNA<sup>25</sup>; ACTTGAT, nucleotides 2,493–2,499 and 5,696–5,702 in M13 DNA<sup>25</sup>; CTTGATA, nucleotides 68–74 in  $\Phi$ X DNA<sup>7</sup>).

In contrast to the gene A protein, the A\* protein cleaves the octamer ACTTGATA. This indicates that the octamer sequence represents the maximum recognition sequence of the A\* protein. The actual recognition sequence is probably less than eight, because the A\* protein has been shown to cleave single-stranded  $\Phi$ X DNA at about 30 different sites<sup>12</sup>.

The possibility that gene A protein is considered to be a nuclease which acts specifically on single-stranded DNA has already been suggested by the finding that the gene A protein nicks supercoiled  $\Phi$ X RFI DNA but not relaxed  $\Phi$ X RF DNA<sup>6,23,26</sup>. Supercoiled DNA has been shown to contain regions of local unwinding, particularly at A+T-rich regions<sup>27</sup>. Interestingly, in the RFI DNAs that are nicked by the gene A protein, the cleavage site is always located in an A+T-rich area (Fig. 5). It is thought that the gene A protein can nick these RFI DNAs, because the recognition sequence is present in a (partially) single-stranded form. However, supercoiled  $\Phi$ X RFI DNA is not nicked by the A\* protein<sup>12,14,23</sup>, indicating that its

**Fig. 5** The nucleotide sequence of the DNA of ΦX174, G4, St-1 and polyoma virus in the region of the gene A protein recognition sequence. The fractions indicate the relative amounts of G and C residues in the different DNA stretches. The ΦX DNA sequence is from Sanger *et al.*<sup>7</sup>, the G4 DNA sequence from Godson *et al.*<sup>36</sup>, the St-1 DNA sequence from Heidekamp *et al.*<sup>10</sup> and the polyoma DNA sequence is from Deininger *et al.*<sup>34</sup>.

recognition sequence is not sufficiently exposed in a single-stranded form. Thus the longer recognition sequence of the gene A protein may be expected to show even less single strandedness in supercoiled ΦX RFI DNA. Nevertheless, supercoiled ΦX RFI DNA is efficiently nicked by the gene A protein. These considerations lead to the conclusion that the gene A protein, in contrast to the A\* protein, can cause unwinding of the DNA double helix at the recognition sequence, which can then be nicked. The unwinding could be driven by the release of (part of) the free energy of the superhelix formation which could take place during the binding of the gene A protein to the ΦX RFI DNA. This unwinding property of the gene A protein is also suggested from the observation that the protein is required for the movement of the replication fork during ΦX DNA replication *in vitro*<sup>5,6</sup>. It seems likely that the DNA unwinding properties of the gene A protein are located in the N-terminal part of the protein chain which is not present in the A\* protein.

The decamer sequence CAACTTGATA is unique in ΦX DNA<sup>7</sup>. It does not occur in M13 DNA<sup>25</sup>, fd DNA<sup>28</sup>, SV40 DNA<sup>29,30</sup>, BKV DNA<sup>31</sup> or pBR322 DNA<sup>32</sup>. However, in polyomavirus DNA, the sequence CAACTTGATA occurs (nucleotides 1,719–1,710 (ref. 33) or 1,737–1,728 (ref. 34)) in the strand with the same polarity as the late mRNAs<sup>33</sup>. The supercoiled polyoma virus component I DNA is not nicked by the gene A protein whereas St-1 RFI DNA in the same reaction mixture is nicked efficiently (F. Heidekamp, personal communication). Comparison of the DNA sequence surrounding CAACTTGATA in polyoma DNA with that of the DNAs of the isometric phages ΦX, G4 and St-1 (Fig. 5) indicates that a characteristic A + T-rich region which is present in the isometric phage DNAs is absent in polyoma DNA. This may explain the

observation that supercoiled polyoma DNA is not nicked by the gene A protein. In single-stranded DNA the gene A protein does not require the A + T-rich region as shown by the present work and the fact that the single-stranded polyomavirus DNA restriction fragment *Hae*III 8, which contains the sequence CAACTTGATA, is cleaved by the gene A protein next to the G residue in this sequence (A.D.M.v.M., unpublished results).

In summary, the successful reaction of ΦX RFI DNA and its initiator protein of DNA replication has been shown to depend on a subtle interplay of the two components of the reaction. The substrate requirements involve (part of) the decamer sequence CAACTTGATA and an adjacent A + T-rich region, which must be present in supercoiled DNA. In supercoiled ΦX RFI DNA this region is sufficiently unwound to bind the gene A protein. This binding causes local unwinding of the DNA double helix which exposes the recognition sequence in a single-stranded form. Subsequently, the gene A protein cleaves one strand, the strand containing the sequence CAACTTGATA. Cleavage occurs at the 3' side of the G residue, and creates a primer for DNA polymerase III holoenzyme to start the rolling circle DNA replication<sup>5</sup>.

We thank Miss H. A. A. M. van Teeffelen for technical assistance, Dr J. H. van de Pol for computer analysis of the ΦX and G4 DNA sequence, P. J. G. F. van Wezenbeek for computer analysis of the M13 DNA sequence, Dr A. J. van der Eb and Dr J. R. Arrand for gifts of polyoma virus DNA, and F. Heidekamp for communicating his unpublished results. The investigation was supported in part by the Netherlands Foundation for Chemical Research (SON), with financial aid from the Netherlands Organisation for the Advancement of Pure Research (ZWO).

## Transition to oscillatory motion in the Taylor experiment

T. Mullin & T. Brooke Benjamin

Mathematical Institute, 24–29 St Giles, Oxford OX1 3LB, UK

Debates about hydrodynamic stability and the origins of turbulence are often based on the phenomena observable in Taylor's experiment<sup>1</sup> on the flow between concentric circular cylinders, the inner of which rotates while the outer is stationary. To reappraise a central aspect of this subject, we report here the effects of annulus length on the limit of stability for various steady cellular flows. For comparatively small values of the aspect ratio  $\Gamma$ , unforeseen behaviour has been observed indicating enormous sensitivity to end effects. In particular, plots of critical Reynolds number  $R_w$  against  $\Gamma$  are sharply peaked, and the form of oscillations arising at the stability limit changes in successive ranges of  $\Gamma$ . The new phenomena are beyond the reach of any present theory, and they highlight the need for caution when transition observations are interpreted.

The variety of phenomena observable in the Taylor experiment can be classified in terms of a Reynolds number  $R$  whose value fixes dynamical similarity for given proportions of the annular space filled by the fluid: say,  $R = \Omega r_1 d / \nu$ , where  $\Omega$  is the angular velocity of the inner cylinder,  $r_1$  its radius,  $d = r_2 - r_1$  the gap width and  $\nu$  the kinematic viscosity of the fluid. At small  $R$  the flow has no detectable longitudinal or radial component. However, when  $R$  is raised into a narrow, quasi-critical range, typically  $< 100$ , the flow develops a cellular structure, remaining steady and axisymmetric but being such that in adjacent cells the fluid particles move in counter-rotating spiral paths. When  $R$  is raised above a higher threshold value, the flow becomes unsteady with its cellular structure perturbed by circumferential travelling waves. As  $R$  increases further, the temporal variations become progressively more complex, exhibiting several incommensurate frequencies, and eventually a turbulent but perhaps still regularly pulsating state of motion is observed. Recent experimental advances<sup>2,3</sup> have renewed interest in these later stages of the transition to turbulence. In particular, the Taylor experiment should be a test of new theoretical concepts<sup>4</sup> concerning the incipience of turbulence.

Most theoretical studies of the Taylor experiment have been simplified by assuming the annulus to be infinitely long. These have given good estimates for the value of  $R$  at which cells first appear but little insight into the process whereby the number of cells is related to the annulus length. Earlier experiments<sup>5</sup> have, however, shown that the steady cellular flows realizable in the second stage of the Taylor experiment are not unique, and that the length-dependent selection process is complex and quite beyond simulation by the idealized model. Moreover, the multiplicity of steady flows possible at sufficiently high  $R$  values includes various 'anomalous' modes which cannot, for any annulus length, be produced by gradually increasing  $R$  from small values<sup>6</sup>. Although these phenomena have all been qualitatively explained by abstract methods of analysis<sup>7,8</sup>, they have not yet been covered by numerical or other constructive calculations. Non-uniqueness complicates the third, travelling-wave stage of the Taylor experiment<sup>9</sup>, and clearly the complicated solution set in this and the second stage will have to be elucidated further before the final transition to turbulence can be properly understood.

We have modified previous apparatus<sup>5</sup> to give finer control of temperature in the fluid and of rotor speed. The end conditions are virtually symmetric, the bottom of the fluid-filled annular space being a fixed wall and the top being the surface of a PTFE collar whose distance  $l$  from the bottom is continuously adjust-

able from 0 to 126 mm. (Previous, otherwise comparable experiments have used a free upper boundary<sup>10,11</sup>.) The radii of the cylindrical boundaries are  $r_1 = 36.9$  mm and  $r_2 = 60.0$  mm, so that the aspect ratio  $\Gamma = l/d$  is variable from 0 to 5.45.

The working fluid for these experiments was an aqueous solution of glycerol, 50:50 by volume, to which a small quantity of a pearly substance was added for flow visualization. Illuminated laterally, the Taylor cells were seen through the transparent outer cylinder as spiralling myriads of light specks, separated by thin dark bands. The extremely sensitive method of visualization revealed both the finest details of a steady flow and the onset of travelling waves when  $R$  was gradually raised to its critical value. A periodic rise and fall of the cell boundaries could then be seen. When established, however, the time-dependent motions were too complex for their spatial forms to be readily appreciated by the unaided observer. For later measurements of wave speeds, a greater amount of the visualizing additive was used, although not enough to affect the mechanical properties of the liquid but still able to produce vivid images of the kind that has often been recorded<sup>2,9</sup>. As a guide to the identification of angular wavenumbers among the different oscillations observed, photographs and a cine-film were used.

The production of various steady cellular flows in this apparatus, including the anomalous modes, has been described previously<sup>5</sup>. The stability of four such flows is now considered: (1) the two-cell mode in which the fluid spirals in the normal way, radially inwards near the end walls; (2) the normal four-cell mode; (3) the three-cell mode which is alternatively realizable with an abnormally spiralling cell at one end or the other; and (4) the abnormal four-cell mode in which each cell spirals oppositely to its counterpart in (2). The main observations involved establishing a particular mode in a steady state for a measured annulus length  $l$ , and then raising the rotor speed in very small steps until travelling waves appeared. In this way the critical value  $R_w$  of  $R$  marking the limit of stability was found as a function of  $\Gamma$ . After each increment of speed, the system was allowed to settle into its respective steady state, and for consistent results in approaching critical speeds the settling times needed to be prolonged far beyond those suggested by Snyder's<sup>10</sup> empirical estimate.

Having established travelling waves at constant amplitude, the rotor speed was then very gradually reduced, with the same precautions about adequate settling times, until the wavy motion ceased. A definite hysteresis, spanned by the interval from  $R_w$  down to a second critical value  $R'_w < R_w$ , was thus observable in most cases. This was manifested by the sudden cessation of previously vigorous oscillations, the hysteresis limit  $R = R'_w$  could be confidently estimated by our visual method. The frequency of the waves,  $f = \omega/2\pi$  Hz, was measured by timing a predetermined large number of periods with a stopwatch.

Figure 1 shows the results for  $R_w$  and  $R'_w$  plotted against  $\Gamma$ , where the most outstanding feature is the set of high peaks in the stability curves for the four different modes of steady axisymmetric flow. For each mode there is an optimal length of the annulus for which the stable range of rotor speeds is most prolonged, and the maximal values of  $R_w$  are surprisingly great. For the two normal modes, these values are in fact  $\sim 18$  times the critical value of  $R$  for the first appearance of cells according to the idealized theory, and  $\sim 15$  times the estimate of  $R_w$  on a similar basis ignoring end effects<sup>12</sup>. Cole<sup>11</sup> has also observed rapid increases in  $R_w$ , to more than double the estimated value, on reductions of aspect ratio  $\Gamma$  below  $\sim 10$ . (His results, however, do not make it clear whether the same cellular mode had been maintained as  $\Gamma$  was varied.) On the other hand, the well defined optimal length for each mode is quite unexpected, and its distinctness suggests that it should not be exclusive to the modes with comparatively few cells.

Fig. 1 Stability limit  $R_w$  and hysteresis limit  $R'_w$  as a function of aspect ratio  $\Gamma$ , for four cellular modes.

The curious ridge broadening the peak in the plot of  $R_w$  against  $\Gamma$  for the normal four-cell mode is associated with occurrence of travelling waves that have azimuthal wave number  $n = 1$  (that is, period  $2\pi$  in the cylindrical polar angle). This 'weak wavy mode', so called by Markho *et al.*<sup>13</sup>, was observed only in this region of Fig. 1. For settings  $\Gamma < 4.10$ , to the left of the ridge, the instability of the normal four-cell mode was manifested as waves with  $n = 2$ , giving rise to periodic oscillations of the upper and lower intercellular boundaries but leaving the central boundary steady. With  $\Gamma$  raised into the range 4.10–4.34, however, the unusual wave-form having  $n = 1$  arose; then oscillations appeared on the central interface but none on the other two. After a further increase of  $\Gamma$  into the range 4.34–4.72 which includes the optimal value, the onset of unsteadiness took the more complicated form of a quasi-periodic motion exciting all four cells, which was comprised from waves with  $n = 1$  and those with  $n = 5$  whose frequency was much higher. This form of motion was visibly quite distinct from the singly periodic motions observed elsewhere. For  $\Gamma > 4.72$ , a singly periodic motion was again encountered, but in this case with  $n = 5$ .

The two-cell mode was observed to follow a simpler pattern of behaviour at its stability locus as shown in Fig. 1. It had access there only to periodic waves with either  $n = 3$  or  $n = 5$ , depending on  $\Gamma$ .

The peaks of  $R_w$  for the two anomalous modes are  $\sim 12\%$  and  $22\%$  lower than those for the normal modes, and this deficiency seems consistent with the comparatively high lower limits also set on their ranges of stability<sup>6</sup>. Over a range of  $\Gamma$  upwards from just below the respective optimal value, each of these modes developed singly periodic travelling waves with  $n = 5$  when  $R$  had been raised gradually to  $R_w$ . In common with the normal

modes, however, they could be switched to wave regimes with other values of  $n$  by means of sudden changes in the rotor speed. Over this range each anomalous mode had the striking property that, after the onset of travelling waves, the normally spiralling cells executed distinct oscillations whereas none was observable in the abnormal cells (at one end for the three-cell mode, and at both ends for the anomalous four-cell mode). In fact, for the four-cell mode, increases in speed beyond the threshold value produced a multiply-periodic wave system disturbing the central interface but still causing no observable oscillations in the end cells.

Over a range to the left of the respective peak in Fig. 1, on the other hand, each anomalous mode exhibited another category of time-dependent motion when  $R$  had been raised to  $R_w$ . The motions were seen to be irregular, featuring slow pulsations of large amplitude but without any well defined low frequency. Because there were some moderately energetic components at higher frequencies, the observed motions might perhaps qualify as a primitive form of turbulence. However, their lack of resemblance to any familiar example of turbulence, including flows in our apparatus at much higher  $R$ , makes us wary of such a description.

For conditions at the left-hand end of Fig. 1, the irregular motions grew large enough to cause coalescence of the central and abnormal end cells, whereupon the three-cell mode collapsed into the two-cell mode which duly became steady. A similar situation, where the onset of waves resulted in the eventual collapse of the flow structure, was found for the abnormal four-cell mode in a range of  $\Gamma$ , 3.52–4.07, to the left of the peak in the experimental graph A4. This collapse was into the three-cell mode, which became steady or mildly wavy depending on  $\Gamma$ . Spontaneous mode-jumping in this manner has been described by Coles<sup>9</sup>, referring to arrays of many Taylor cells, but none of his observations exemplified the present case of collapse from an oscillating mode into a steady one.

Most of the observed transitions to time-dependent states of flow evinced appreciable hysteresis, as shown by the experimental plots of  $R'_w$  against  $\Gamma$  (dashed curves in Fig. 1). An interesting feature of the graphs is that the amount of hysteresis,  $R_w - R'_w$ , varies quite abruptly with  $\Gamma$  in certain places, which correspond to the changes that were observed among the types of wavy motion arising at  $R = R_w$ . This feature is particularly prominent near the peak of the graphs for the normal four-cell mode. It had seemed plausible that the irregular, multi-component oscillations of the anomalous modes at annulus lengths less than the optimal would have a large hysteresis, and

Fig. 2 Dimensionless angular speed of travelling waves that appear at stability limit  $R_w$ .

that as  $R$  was reduced they might first relax into periodic oscillations before the unsteady motion ceased at  $R = R'_w$ ; but no such behaviour was detected experimentally.

The transition has great sensitivity to end effects; but in contrast another, more easily recorded property was found to be surprisingly insensitive to them. Expressed as a multiple of  $\Omega$ , the angular speed  $\omega/n$  of the observed travelling waves turned out to be nearly independent of  $R$ , as shown in Fig. 2 which includes values of  $\omega/n\Omega$  from all our measurements of frequency. The mean value is about 0.32, which is unexpectedly close to corresponding values found previously by others from observations in apparatus with  $\Gamma$  an order of magnitude larger, for example the value 0.34 found by Coles<sup>9</sup>. Considered alone, this property might thus be deceptive as regards the overall importance of end effects.

We thank the SRC for support, and the Department of Engineering Science at Oxford for laboratory facilities.

## Complete vitrification in pure liquid water and dilute aqueous solutions

Peter Brüggeller & Erwin Mayer

Institut für Anorganische und Analytische Chemie, Universität Innsbruck, A 6020 Innsbruck, Austria

Pure water can only be vitrified by the very slow condensation of vapour on a metal surface maintained at very low temperatures<sup>1,2</sup>. Attempts to form vitreous ice by rapid cooling of liquid water invariably lead to formation of ice  $I_h$  (ref. 3). (Pryde and Jones<sup>4</sup> did report a heat capacity change of rapidly cooled water at 126 K which they attributed to a glass transition, but could not reproduce this result in subsequent experiments.) Dilute aqueous solutions in contrast to concentrated aqueous solutions<sup>5</sup> behave similarly to water and separate during freezing, even with the highest cooling rates available, into pure ice and concentrated solute<sup>6</sup>. We report here that macroscopic parts of samples of pure liquid water and of dilute aqueous solutions can be vitrified completely by jet-freezing of micrometre-sized aqueous droplets distributed in *n*-heptane as an emulsion—the resulting supercooling effect of  $\sim 40$  K being essential for vitrification<sup>7</sup>.

The formation of vitrified ice from pure liquid water is demonstrated by the differential thermal analysis (DTA) warm-up curve of a jet-frozen emulsion of pure water (Fig. 1b). The exothermic peak at 150 K occurs at the temperature reported for the devitrification of amorphous ice prepared from water vapour<sup>8</sup>. The endothermic peak at 183 K is due to an *n*-heptane impurity. Jet-frozen 0.10 M  $\text{CuCl}_2$  solutions (chosen for ESR requirements) gave similar warm-up curves with the exothermic peak also occurring at 150 K. We have not observed clearly a glass transition. Only a faint endothermic inclination at  $\sim 138$  K in warm-up curves of jet-frozen water and of 0.10 M  $\text{CuCl}_2$  solutions might come from the glass transition of the vitreous phase which compares well with the glass transition temperature of vapour deposited amorphous ice<sup>8</sup>. The glass transition will be unmistakable only in vitreous samples with little or no crystalline impurity, and investigations of vitreous ice formed from water vapour seem to confirm this<sup>8</sup>.

**Fig. 1** *a*, X-ray diffraction pattern ( $\text{Cu K}\alpha$ ) of a jet-frozen emulsified 0.10 M  $\text{CuCl}_2$  solution, heated consecutively from 95 K to 160 and to 220 K. *b*, DTA warm-up curve of jet-frozen emulsified pure liquid water. Heating rate  $6^\circ \text{min}^{-1}$ . The low-temperature DTA apparatus was similar to that used by Rasmussen<sup>9</sup>. The NiCr–Konstantan combination was used as thermocouple and the bottom parts of thin-walled 10-mm diameter NMR tubes were used for sample and reference, and for temperature measurement. About 100 mg of sample were diluted with 300 mg  $\text{CaCO}_3$  and transferred quickly into the precooled DTA apparatus.  $\text{CaCO}_3$  was used as inert reference and in the tube for temperature measurement. Samples were prepared as follows: the emulsion was prepared by dissolving 0.030 g Span 65 (sorbitan tristearate) in 9 ml *n*-heptane, adding 1 ml pure liquid water (*b*) respectively 1 ml 0.10 M aqueous  $\text{CuCl}_2$  solution (*a*) and sonifying the mixture. Droplet size depends strongly on sonifier energy and was adjusted to 1–5  $\mu\text{m}$  (larger droplets supercool insignificantly<sup>7</sup> and the ESR spectra indicated strong aggregation). 5 ml emulsion were jetted through a thick-walled glass tube with a 50  $\mu\text{m}$  aperture, using 100 atm working pressure, into 120 ml of vigorously stirred liquid ethane cooled to  $\sim 90$  K. We preferred ethane to propane as cryomedium because ethane can be pumped off quantitatively at 120 K. For DTA and X-ray experiments *n*-heptane was removed nearly completely by washing the frozen droplets several times with liquid ethane at 110 K. After pumping off the remaining ethane at 120 K the frozen droplets were transferred quickly with a liquid-nitrogen cooled spoon into the precooled apparatus. During the whole procedure the droplets were warmed at most to 130 K. At liquid-nitrogen temperatures special care has to be taken to prevent accumulation of liquid oxygen in the cryomedium.

The amount of the vitrified material was determined by calibration with a 50% w/v vitrified glycerol solution. Devitrification of a 50% w/v glycerol solution produces according to Rasmussen and Luyet<sup>9,10</sup> a 73% w/v glycerol solution. We obtain an estimate by comparing the peak areas. To reduce errors both standard and sample were diluted equally with  $\text{CaCO}_3$  and an amount of vitrified glycerol was chosen with a similar signal intensity to our vitrified samples. We found that jet-frozen water/heptane emulsions contain 13% vitrified ice. For jet-frozen emulsified 0.10 M  $\text{CuCl}_2$  solutions a slightly higher value of 16% devitrified ice was obtained after several determinations. This only slightly higher value indicates that the freezing behaviour of a 0.10 M solution is comparable with the freezing behaviour of pure water, the small amount of additional devitrification coming from more concentrated vitrified parts of the solution.

We also investigated the vitrification of aqueous emulsions by X-ray diffraction and ESR spectroscopy. The X-ray diffraction pattern of ice allows us to differentiate between the phases  $I_h$  and  $I_c$  and mixtures of these, by the relative intensities of the three strong reflexes of ice  $I_h$  (for Cu  $K\alpha$ :  $2\theta = 22.8^\circ$ ,  $24.3^\circ$  and  $25.9^\circ$ ) and the strong reflex of ice  $I_c$  ( $2\theta = 24.3^\circ$ )<sup>11,12</sup>. The presence of vitreous components in a partially crystalline sample can be followed by the formation of ice  $I_c$  at the devitrification temperature and the relative increase of the reflex of ice  $I_c$  at  $2\theta = 24.3^\circ$ . Figure 1a shows the characteristic part of the X-ray diffraction pattern of a jet-frozen 0.10 M  $\text{CuCl}_2$  emulsion. The diffraction pattern at 95 K indicates a mixture of ice  $I_h$  and  $I_c$ . At 160 K a drastic increase of the reflex at  $2\theta = 24.3^\circ$  indicates the formation of ice  $I_c$  by devitrification of an amorphous phase. At still higher temperatures, ice  $I_c$  transforms to ice  $I_h$  and at 220 K only the reflexes of  $I_h$  are visible. Our experimental conditions inevitably lead to contamination of the original jet-frozen sample by ice  $I_h$  due to condensation of water vapour during the preparation and transfer of the sample to the X-ray camera, therefore, the resulting X-ray diffraction pattern at 95 K will contain an unknown amount of ice  $I_h$ .

The freezing behaviour of the solute in a dilute solution was studied by ESR spectroscopy. Whereas most other spectroscopic techniques are only sensitive to short-range order (that is,

**Fig. 2** Low temperature (113 K) ESR spectra of: *a*, 0.10 M  $\text{CuCl}_2$  solution, containing 50% (v/v) glycerol for vitrification; *b*, 1.5 M  $\text{CuCl}_2$  solution vitrified as above; *c*, 0.10 M  $\text{CuCl}_2$  slowly frozen by immersion in liquid nitrogen.

**Fig. 3** Low temperature (113 K) ESR spectra of: *a*, 0.10 M  $\text{CuCl}_2$  solution spray-frozen into liquid propane cooled to  $\sim 80$  K. The reported technique<sup>15</sup> was slightly modified: the solution was sprayed into 50 ml of stirred propane and the suspension filtered at 90 K. *b*, A jet-frozen 0.10 M  $\text{CuCl}_2$  emulsion using optimized conditions as described in Fig. 1.

the first hydration sphere), ESR is sensitive to comparatively long range order effects due to the  $1/r^3$  dependence of dipolar interaction<sup>13</sup>. With our system we can differentiate clearly between a 0.10 and a 1.5 M vitrified solution (Fig. 2*a,b*). We used ESR spectroscopy to maximize the various parameters such as cooling conditions and droplet size and found the spectra invaluable for assessing qualitatively the relative amounts of phase separated crystalline and of vitrified material. We used a 0.10 M aqueous  $\text{CuCl}_2$  solution as our ESR test system because: (1) the spectra representing the two extremes—perfect vitrification and complete phase separation—are shown in Fig. 2*a* and *c* and are separated sufficiently for evaluation. (2) At a concentration of 0.10 M the ESR spectrum was the most sensitive to the segregation of ice during the freezing process. At higher concentrations the ESR signal begins to broaden due to dipole-dipole interactions as shown in Fig. 2*b*. At lower concentrations the spectra of glycerol vitrified solutions are nearly identical to the ESR spectrum in Fig. 2*a*. Therefore even drastic segregation of ice from a very dilute solution such as  $10^{-3}$  M, resulting in a dramatic increase of the solute concentration, will not show up in the ESR spectrum. Figure 3*b* shows the ESR spectrum of a jet-frozen emulsion in the 'best' conditions for vitrification. These conditions were identical with the freezing conditions of the pure liquid water sample in Fig. 1*b*. The ESR spectrum is very similar to the spectrum of the perfectly vitrified solution in Fig. 2*a*. Some aggregation of  $\text{CuCl}_2$  is indicated by a broad hump at 2,940 G.

The ESR spectra of jet-frozen 0.10 M  $\text{CuCl}_2$  emulsions display drastic spectral changes with increasing temperature which are irreversible. In Fig. 4 the ESR spectra of a sample warmed for 30 min consecutively to 153 K (*b*), 173 K (*c*) and 193 K (*d*) have to be compared with the spectrum of the original sample at 113 K (*a*). At 153 K the ESR signal starts to broaden approaching within 30 min the width of a 1.5 M vitrified solution (compare with Fig. 2*b*). The increase of the signal at 2,940 G indicates the formation of a highly concentrated  $\text{CuCl}_2$  phase.

At higher temperatures the amount of concentrated  $\text{CuCl}_2$  increases. Evidence from DTA warm-up curves and from the X-ray diffraction patterns of Fig. 1a clearly indicates the process causing the irreversible change of the ESR spectra with temperature. The start at 153 K correlates well with the devitrification temperature determined by DTA. At this temperature ice  $I_c$  (shown by the X-ray diffraction pattern) starts to separate from the vitrified solution, the remaining  $\text{CuCl}_2$  becoming more and more concentrated.

From the theory<sup>3</sup> of the homogeneous nucleation of freezing, the cooling rate necessary for vitrifying a  $\mu\text{m}$ -sized droplet of water was estimated to be  $>10^{10} \text{ K s}^{-1}$  and was considered to be unattainable in practice. To compare our technique with others and to obtain some idea of the relative effects of emulsification and of jet-freezing we investigated the freezing methods usually applied in freeze etching. These methods were too slow to give observable DTA devitrification peaks, and we therefore used ESR spectroscopy. Dropping of  $1 \mu\text{l}$  droplets into liquid Freon at 120 K (the "standard freezing method"<sup>14</sup>—cooling rates up to  $10^3 \text{ K s}^{-1}$ ), yields complete aggregation and the ESR spectrum of a frozen  $0.10 \text{ M CuCl}_2$  solution is identical with the spectrum in Fig. 2c. Even the much faster cooling methods developed by Bachmann and Schmitt<sup>15</sup> (spray-freezing and jet-freezing into liquid propane at 77 K, estimated cooling rates of  $10^5 \text{ K s}^{-1}$ ) do not prevent segregation of the solute from the solvent. The ESR spectrum of a spray-frozen  $0.10 \text{ M CuCl}_2$  solution in Fig. 3a shows mainly aggregated  $\text{CuCl}_2$  and only a minor amount of less concentrated  $\text{CuCl}_2$  is indicated by the shoulder at 3,150 G. Jet-freezing of a  $0.10 \text{ M CuCl}_2$  solution through a  $20 \mu\text{m}$  aperture with 10 atm working pressure into liquid propane gives similar results to spray-freezing. We also tried to obtain a comparison with the cooling methods applied in splat-cooling of liquid metals and alloys<sup>16</sup> by jetting a  $0.10 \text{ M CuCl}_2$  solution through a  $10 \mu\text{m}$  aperture with 100 atm working pressure onto a copper plate cooled to 77 K. The jet was moved as quickly as possible over the surface of the cooled copper plate and its speed was calculated to be  $\sim 100 \text{ m s}^{-1}$  from the diameter of the aperture and consumption of liquid. Although this experiment was not performed using strict splat-quenching conditions we

believe it to be comparable with the 'gun-technique'<sup>16</sup> because of the high speed and small diameter of the jet. The ESR spectrum of the resulting frozen solid indicated complete aggregation. Apparently splat-cooling techniques give very low cooling rates for water and dilute aqueous solutions due to the low conductivities of water and ice.

We estimated our cooling rate by jet-freezing a non-emulsified  $0.10 \text{ M CuCl}_2$  solution, using otherwise identical conditions (glass capillary with  $50 \mu\text{m}$  aperture, 100 atm working pressure into liquid propane at 77 K). The ESR spectrum shows a clear improvement over the ESR spectrum of a spray-frozen sample in Fig. 3a, the signals at 3,050 and 3,150 G being of equal size. We therefore assume the cooling rate to be between  $10^5$  and  $10^6 \text{ K s}^{-1}$ . The further improvement with emulsified solutions in Fig. 3b demonstrates clearly the importance of emulsification and of the resulting supercooling effect for the vitrification of water and dilute aqueous solutions.

We thank Dr L. Bachmann for directing our attention towards this research and for helpful discussions.

## Lu–Hf total-rock isochron for the eucrite meteorites

P. J. Patchett\*† & M. Tatsumoto\*

\* US Geological Survey, Denver Federal Center, Denver, Colorado 80225

† Colorado School of Mines, Golden, Colorado 80401

The isotope  $^{176}\text{Lu}$  (2.6% of natural lutetium) decays by  $\beta^-$  to  $^{176}\text{Hf}$ , with a long half life. We present here the first Lu–Hf isochron. The eucrite meteorites, a suite of planetary igneous rocks of known age, 4,550 Myr, define a 10-point total-rock isochron with a slope of  $0.0934 \pm 40$ , leading to a value of  $3.53 \pm 0.14 \times 10^{10}$  yr for the  $\beta^-$ -decay half life of  $^{176}\text{Lu}$ . The isochron intercept of  $0.27973 \pm 12$  gives the initial  $^{176}\text{Hf}/^{177}\text{Hf}$  for the inner Solar System at the time of accretion.

Previous geochronological use of the  $^{176}\text{Lu}$ – $^{176}\text{Hf}$  decay scheme involved REE-rich minerals<sup>1,2</sup> in attempts to determine the half life. Faure<sup>3</sup> summarized all physical determinations and suggested a best estimate of  $3.5 \pm 0.2 \times 10^{10}$  yr. However, because  $^{176}\text{Lu}$  is an odd Z-odd N nuclide, then a branching decay is theoretically possible. Dixon *et al.*<sup>4</sup> set an approximate upper limit of 3% on the electron capture to  $^{176}\text{Yb}$ , but to date this possible decay has been neither clearly substantiated nor disproved. It has also not been clearly shown that the Lu–Hf method can be used in isotope chronology and geochemistry.

Using a wide variety of petrological and geochemical criteria, the eucrites constitute a coherent group of cumulate and noncumulate igneous rocks (brecciated to varying degrees), which may have come from a single-parent asteroid<sup>5–7</sup>. In isotope geochemistry, the eucrites are important because they seem to have been produced during a major planetary differentiation 4,550 Myr ago, and to have been isotopically mainly

Fig. 4 Low temperature (113 K) ESR spectra of a jet-frozen  $0.10 \text{ M}$  aqueous  $\text{CuCl}_2$ /n-heptane emulsion: a, warmed at most to 113 K; b, c and d warmed consecutively for 30 min to 153 K, 173 K and 193 K respectively.

undisturbed since then. Extensive Rb–Sr (refs 8, 9), U–Pb (ref. 10), and Sm–Nd (refs 10–14) studies confirm this, and also that the samples had essentially the same  $^{87}\text{Sr}/^{86}\text{Sr}$  and  $^{143}\text{Nd}/^{144}\text{Nd}$  ratios 4,550 Myr ago. Thus although the eucrites may well have been derived from a single-parent body, this is not a necessary assumption for the present Lu–Hf total-rock isochron exercise, because they have already been shown to be isotopically concordant for the Rb–Sr and Sm–Nd systems, both in age and initial ratio.

Of the 10 samples studied, Stannern, ALHA 77302, Béréba, Nuevo Laredo, Pasamonte, Sioux County and Juvinas are non-cumulate eucrites, consisting of variously brecciated fine- to medium-grained basaltic material. Serra de Magé, Moore County and Moama are cumulate rocks<sup>6</sup>, consisting mainly of coarse-grained unbrecciated pyroxene and plagioclase.

The analytical method is described fully elsewhere<sup>15</sup>. Bomb dissolutions on the disaggregated meteorites were used. The samples were then separated into two aliquots, and mixed  $^{176}\text{Lu}$ – $^{180}\text{Hf}$  spike added to one fraction. Chemical separation for Hf involved three ion-exchange columns and the overall chemical yield was 90%. Lu was not well separated from Yb, but the latter is more volatile and can be easily burned off the sample in the mass spectrometer. Overall blanks were  $<0.1$  ng for Lu and Hf; even for the most Lu, Hf-poor sample, Moama, the sample/blank ratio is  $>600$  for both elements, and hence no corrections for blanks were made. At most, this could result in a 0.15% bias in isochron slope; this is 30 times less than the  $2\sigma$  slope uncertainty, and is clearly insignificant.

Lu was measured on Ta side filaments using a Re centre filament. Hf was measured using a triple Re filament assembly.  $^{179}\text{Hf}/^{177}\text{Hf} = 0.7325$  was used for normalization. The mean value for 25 runs on the Johnson Matthey Hf standard JMC 475 is  $0.282195 \pm 15$  ( $2\sigma$ ) (see Fig. 1). We suggest JMC 475 as an international mass spectrometric Hf standard, and aliquots prepared from a single batch are available on request from Denver. From 1  $\mu\text{g}$  of Hf, a total signal of  $0.5 \times 10^{-11}$  A can be maintained for over 3 h, leading to precision of 0.01–0.03% on  $^{176}\text{Hf}/^{177}\text{Hf}$ .

The low Hf contents of the cumulate eucrites Serra de Magé, Moore County and Moama necessitated use of ion counting for Hf composition runs on these samples. Our two-stage mass spectrometer is equipped with a multiplier as collector, and a pulse-height discriminator to detect pulses. JMC 475 was run using ion counting on the two-stage mass spectrometer immediately before each Hf run on the cumulate eucrites, because of possible bias introduced by using a different machine and by variations in multiplier peak shape. Adjusting the higher values measured for JMC 475 by counting to 0.282195 resulted in corrections of  $-0.00012$  being applied to the Hf compositions of Moore County and Moama, and  $-0.00028$  to Serra de Magé. Corrections for Yb interference in Hf runs were never necessary, and in normal samples, Lu was also absent for all but the first 10–30 ratios of a run. For the samples measured by count-

**Fig. 1**  $^{176}\text{Hf}/^{177}\text{Hf}$  ratios for the Johnson Matthey standard JMC 475 during the eucrite study. The overall mean is  $0.282195 \pm 15$  normalized to  $^{179}\text{Hf}/^{177}\text{Hf} = 0.7325$ .

**Fig. 2** Lu–Hf isochron for the eucrite meteorites. ALHA 77302 is excluded from the regression treatment. Slope,  $0.0934 \pm 0.0040$ ; intercept,  $0.27973 \pm 0.00012$ ; MSWD, 2.50.

ing, corrections for Lu were applied, amounting to absolute downward adjustments in  $^{176}\text{Hf}/^{177}\text{Hf}$  of 0.00002–0.00008.

Lu–Hf isotopic results are listed in Table 1. The Lu/Hf ratio decreases with increasing Lu and Hf concentrations, so that the cumulate eucrites, depleted in trace elements, have Lu/Hf much higher than the noncumulate eucrites. However, over the Hf concentration range 2.4 p.p.m. (Stannern) to 0.8 p.p.m. (Juvinas), the Lu/Hf ratio changes only from 0.18 to 0.25, and there is thus strong coherence between the two elements. In the cumulates, where the residual liquid from crystallization of the pyroxene and plagioclase has been at least partly excluded, this coherence disappears. The cumulate samples (Moama, Lu/Hf = 0.82) presumably became more depleted in Hf than they did in Lu because Hf was more strongly concentrated in the residual liquid. This marked relative depletion of Hf in rocks which do not contain their lowest-melting components, such as cumulates, or residues of partial melting, seems to be an important characteristic of Lu–Hf geochemistry.

We have measured the isotopic composition of Lu in three samples, and find it to be within error of the terrestrial JMC 320 standard ( $37.701 \pm 0.028$ ), particularly taking into account the fact that fractionation cannot be normalized for this two-isotope element. Using large  $\text{Lu}^+$  ion beams from triple filaments, and a Faraday cup collector, we consistently measure  $\sim 37.70$  for JMC320, and 37.55–37.74 for natural samples, depending on fractionation conditions. We cannot reproduce the low values of McCulloch *et al.*<sup>19</sup>, obtained using an electron multiplier, and because we can see no way to correct our measurements objectively for mass fractionation, we have internally standardized all our calculations by using the measured value of  $37.701 \pm 0.028$  for natural  $^{175}\text{Lu}/^{176}\text{Lu}$ . If this ratio is used in any future Lu–Hf geochronology, then all errors will mutually cancel, because the decay constant determined here is based on an isochron whose slope is calculated using the same Lu isotopic composition.  $^{180}\text{Hf}/^{177}\text{Hf} = 1.88651$  (normalized to  $^{179}\text{Hf}/^{177}\text{Hf} = 0.7325$ ) was used for all natural Hf.

Except for the Antarctic eucrite ALHA 77302, the analyses define an isochron (Fig. 2). To increase precision on the initial  $^{176}\text{Hf}/^{177}\text{Hf}$  value, both Stannern results have been included in the regression<sup>16</sup>. The MSWD value of 2.50 suggests a small degree of scatter beyond analytical uncertainties (see Fig. 3), and the  $2\sigma$  errors in slope and intercept (Fig. 2) were obtained by multiplication of the *a priori* uncertainties with  $\sqrt{\text{MSWD}}$  (ref. 16).

ALHA 77302 was analysed twice, and lies clearly above the isochron (Figs 2, 3). The sample was never homogenized, so that the two results are slightly different, with correlated Lu/Hf and  $^{176}\text{Hf}/^{177}\text{Hf}$ . ALHA 77302 has Lu and Hf concentrations very similar to Pasamonte, Nuevo Laredo and Béréba, and distinctly

Table 1 Lu-Hf isotopic data

|               | Lu (p.p.m.) | Hf (p.p.m.) | $^{175}\text{Lu}/^{176}\text{Lu}^*$ | $^{176}\text{Lu}/^{177}\text{Hf}^\dagger$ | $^{176}\text{Hf}/^{177}\text{Hf}^*$ |

\* In-run errors are  $2\sigma_m$ .

† Error includes in-run uncertainties from spiked Lu and Hf runs, an estimated 0.04% uncertainty on run-to-run Lu mass fractionation, and uncertainties on Lu and Hf spike concentration.

‡ Hf composition measured using ion counting on a different mass spectrometer. As a result of standards measured at the same time, Serra de Magé Hf composition has been corrected by  $-0.00028$ , and Moore County and Moama by  $-0.00012$  to correspond to the other results.

lower than Stannern (Table 1). The regular decrease of Lu and Hf upwards along the isochron suggests that the Hf isotopic composition of ALHA 77302 is correct and original (that is similar to Pasamonte, Nuevo Laredo and Béréba), but that the Lu/Hf ratio has been disturbed in post-crystallization time. It seems possible that ALHA 77302 has lost Lu in the recent past, perhaps while embedded for a long time period in the Antarctic ice. The only alternative explanation, that the Hf isotopic composition has been contaminated, is unlikely because any Hf available in quantity on the Earth is probably no more radiogenic than  $^{176}\text{Hf}/^{177}\text{Hf} = 0.284$  (unpublished data), so that a large proportion of such Hf would be needed to raise ALHA 77302 above the isochron. However, we have not conducted leaching experiments on this eucrite.

The intercept of the isochron,  $0.27973 \pm 12$ , gives the  $^{176}\text{Hf}/^{177}\text{Hf}$  of the eucrites at 4,550 Myr, assuming that the age established by other methods can be used for Lu-Hf. As in the case of Nd, it is reasonable, in the absence of evidence to the contrary, to use this value as the primordial Hf isotopic composition for the planets of at least the inner Solar System. At present, however, the chondritic and bulk Earth Lu/Hf ratios are very poorly known, so that isotopic evolution lines cannot be drawn accurately until more data become available. This lack of knowledge is the result of Lu having been analysed with other REE, and Hf usually separately in studies of Zr-Hf fractionation. Our duplicated Hf concentration for Stannern (2.36 p.p.m.) disagrees not only with the neutron activation data of Ehmann *et al.*<sup>17</sup> (1.26 p.p.m.), but also with the isotope

dilution results of Shima<sup>18</sup> (1.23 p.p.m.). This discrepancy can probably only be accounted for by sample heterogeneity, but if our Hf contents of Pasamonte and Stannern are combined with the Zr data of Ehmann *et al.*<sup>17</sup>, then normal Zr/Hf ratios of 35 and 40 are obtained, in contrast to the anomalous 52 and 75 which these authors find using their own Hf contents.

The slope of the isochron,  $0.0934 \pm 0.0040$ , can be used to calculate the  $\beta^-$ -decay constant of  $^{176}\text{Lu}$ , assuming that the total-rock eucrites have been isotopically undisturbed since 4,550 Myr (refs 7-13). The following values are obtained:

$$\lambda^{176}\text{Lu}(\beta^-) = 1.962 \pm 0.081 \times 10^{-11} \text{ yr}^{-1}$$

$$t_{1/2}^{176}\text{Lu}(\beta^-) = 3.53 \pm 0.14 \times 10^{10} \text{ yr}$$

These  $2\sigma$  errors include the scatter component on the isochron; if only the *a priori* uncertainty<sup>16</sup> is used, then the uncertainties on  $\lambda$  and  $t_{1/2}$  are reduced to 0.051 and 0.081 respectively.

The weighted mean of five physical half life determinations made since 1960 (summarized in ref. 3) is  $3.54 \pm 0.11 \times 10^{10} \text{ yr}$ ; this is unchanged if the earlier geological determination<sup>2</sup> of  $3.3 \pm 0.5 \times 10^{10} \text{ yr}$  is included. The agreement between the mean of the physical determinations and the present value based on a Lu-Hf isochron is impressive, and suggests that the value  $3.53 \times 10^{10} \text{ yr}$  for the half life (corresponding to  $\lambda = 1.96 \times 10^{-11} \text{ yr}^{-1}$ ) can now be adopted.

We have ignored the possibility of a minor electron-capture decay of  $^{176}\text{Lu}$  to  $^{176}\text{Yb}$ , so that our half life may be slightly too long. Even if the electron capture does occur, any errors in the age determination will be cancelled out if the half life based on the eucrite isochron is used in future work. This is because the percentage effect on age of an unaccounted-for minor branching decay is essentially linear with time when the decay is slow, as for  $^{176}\text{Lu}$ . If the electron-capture decay can be confirmed and its proportion fixed, then ages calculated using the half life determined here will not need adjustment.

We have established here the usefulness of the  $^{176}\text{Lu}$ - $^{176}\text{Hf}$  decay scheme in isotope chronology, and shown that the igneous eucrite meteorites define an isochron, the slope of which allows the  $\beta^-$ -decay constant of  $^{176}\text{Lu}$  to be determined. The initial  $^{176}\text{Hf}/^{177}\text{Hf}$  ratio of the eucrites at 4,550 Myr probably applies to the Solar System generally, and will be of great importance in calculations of the isotopic evolution of planetary bodies and meteorites.

We thank R. S. Clarke, P. Pellas, C. J. Allègre, C. B. Moore and J. F. Lovering for meteorites, and especially K. Yanai for ALHA 77302. We thank Dan Unruh and Noboru Nakamura for helpful comments. This work was funded by NASA inter-agency transfer order T-783H.

## Is the Hercynian belt of Brittany a major shear zone?

Denis Gapais & Claude Le Corre

Centre Armoricain d'Etude Structurale des Socles (CNRS),  
Université de Rennes, avenue du Général-Leclerc, 35042 Rennes  
Cédex, France

**In the Hercynian belt of Brittany (France), large localized shear zones indicate dextral transcurrent shearing. In this letter regional Hercynian structures and their relationships with shearing are considered and information obtained by quartz fabric analysis in the central part of the belt, outside the major shear zones, is presented. Fabric patterns show that a dextral shear component is associated with Hercynian penetrative deformation. Existing geological data are reconsidered in the light of these results, and the extent to which the Hercynian belt of Brittany can be regarded as a 'major shear zone' is discussed.**

The Hercynian belt of Brittany comprises different structural domains which are separated by major crustal discontinuities<sup>1</sup> expressed as transcurrent shear zones (Fig. 1). Within this segment of the west-European Hercynides, Central Brittany is an essentially Hercynian domain<sup>2,3</sup> characterized by structures which follow a roughly east-west trend (Fig. 1). In Central Brittany tectonic structures show the effects of (1) a roughly north-south shortening, (2) diapiric ascent of Hercynian granites, and (3) a dextral transcurrent shearing. Two basic geodynamic models, which involve mainly large-scale transcurrent shearing<sup>4</sup> or north-south compression<sup>1</sup>, have been proposed to account for Hercynian deformation in Central Brittany. In fact, the problem of the bulk deformation regime (coaxial or non-coaxial) is not at all clear. Recent studies have shown that, when developed during shearing, crystallographic fabrics of quartz are generally asymmetric and can be used to deduce the sense of shearing (see ref. 5). Perhaps the first clear field indication of a close relationship between dextral shearing and Hercynian deformation in Central Brittany was that reported by Bouchez and Blaise<sup>6</sup> and Bouchez<sup>7</sup>, on the basis of quartz fabric data. Their results, however, are of very local applicability. Furthermore, clear microtectonic evidence of shearing is lacking within large parts of the belt<sup>8–10</sup>. This has led to a modified geodynamic model<sup>9</sup> in which effects of shearing are mainly restricted to the mapped shear zones (Fig. 1), and remain relatively minor compared with a north-south compression.

Central Brittany is bounded to the north by a rigid continental block, which has been stable since the end of the Proterozoic (see, for example, Mancelian granites) and only slightly affected by the Hercynian orogeny. To the south lies a crystalline block affected mainly by Siluro-Devonian tectono-metamorphic events<sup>1</sup>. Both the northern and the southern limits of Central Brittany are defined by major ductile fault zones, the North and South Armoricain shear zones<sup>1,12–16</sup>. These shear zones, which have a long and complex structural history<sup>1,15,16</sup>, have acted as dextral strike-slip fault zones up to late Hercynian

times<sup>14,15,17,18</sup>. Hercynian plutonism<sup>19,20</sup> is concentrated along these shear zones (Fig. 1).

Within Central Brittany, deformation of the sedimentary rock (Proterozoic and Palaeozoic) is mainly expressed as a regional cleavage, generally subvertical, and associated with large-scale folding. Folds are generally upright with low amplitudes<sup>9,10,21</sup>. Fold axes are always subhorizontal or gently plunging. The cleavage is parallel to the principal plane (xy) of the finite strain ellipsoid, and generally exhibits a mineral elongation lineation parallel to the x axis of the finite strain ellipsoid<sup>8,22</sup>. This principal extension direction is parallel, or nearly so, to the regional fold axes. The regional trend of folds and cleavage trajectories varies from west-southwest to east-southeast when moving eastwards through the belt<sup>3</sup>. Local data relating to finite strain (refs 7–9, 11, 22, and S. K. Hanmer, personal communication) indicate a large range of possible shapes of the finite strain ellipsoid. However, when present, stretching on the intermediate axis (y) remains generally weak or moderate. Plane strain ellipsoids are common and even constrictive finite strain is observed.

The axial region of Central Brittany appears as a zone of relatively weak deformation. Zones of more intense deformation are found on moving north or south, towards the North and South Armoricain shear zones. Thus, across the area between Rennes and the southern branch of the South Armoricain shear zone (Fig. 1), we have shown that strain intensity increases towards the south, as a result of Hercynian deformation<sup>8,9,11</sup>. We have also shown<sup>8,9,11,23</sup> that this regional strain gradient is associated with an increase of metamorphism towards the south<sup>3</sup>.

The Hercynian granites were demonstrably intruded during penetrative deformation<sup>2,3,11</sup>. Regional patterns of strain and metamorphism change in the vicinity of plutons (see Fig. 2). Local perturbations can also be observed around pre-Hercynian bodies (for example, Mancelian granites), as a result of their rigid behaviour relative to the country-rocks during the Hercynian orogeny.

Fabrics and optical microstructures of quartz have been studied in detail within a quartzitic series (Armorican quartzite) of lower Ordovician age. Results given in full elsewhere<sup>15</sup>

**Fig. 1** Simplified geological map of Brittany. The large-scale movements are not precisely determined and arrows indicate only a regional dextral shear component. ①, St Georges-sur-Loire Synclinorium (the inset corresponds to the area of Fig. 2); ②, Sud de Rennes Synclines; A, North Armoricain shear zone; B + C, South Armoricain shear zone (B, northern branch; C, southern branch).

Fig. 2 Geological map of the western part of the St Georges-sur-Loire Synclinorium and variations of fabrics and optical microstructures of quartz within the Armorican quartzite. The dotted line indicates the approximate biotite isograd. The schematic fabric diagrams represent the characteristic  $c$  axes and  $\langle a \rangle$  axes patterns, as inferred from detailed texture goniometry study<sup>10,11</sup>. These patterns indicate a dextral shear component. In the field, the cleavage (dotted line on pole figures, foliation in quartzites) is subvertical, trends roughly N 110°, axial-plane of regional folds. The shear component is acting within a subvertical plane, along a subhorizontal direction.

were obtained from the western part of the St-Georges-sur-Loire Synclinorium (Figs 1 and 2). This Hercynian structure is bounded to the west by Hercynian leucogranites. Associated thermal anomalies are revealed by biotite isograds (Fig. 2). Moving westwards along the southern limb of the synclinorium, an increase of intracrystalline deformation and dynamic recrystallization is observed, leading to a fine-grained quartz mylonite. This is accompanied by a change in quartz  $c$ -axis fabric from a broad girdle with a maximum near the axis of principal shortening to a crossed-girdle pattern with a maximum near the  $y$  axis of the finite strain ellipsoid (Fig. 2). This deformation gradient is attributed to the thermal softening induced by the granites<sup>11</sup>. Quartz fabrics are typically monoclinic. They show a strong maximum of  $\langle a \rangle$  axes oblique with respect to the principal stretching direction  $x$ , and also unequally populated girdles of  $c$ -axes. Such fabrics indicate a dextral shear component<sup>5,10,24</sup> within a subvertical plane, irrespective of the microstructures exhibited by the quartzites (Fig. 2). In some of the quartzites, the occurrence of shear bands and of sigmoidal shadow-zones around rigid objects give further evidence of dextral shearing<sup>10</sup>. Our observations infer that regional shortening and emplacement of granites took place during shear deformation. The leucogranites are themselves penetratively sheared and stretched along the regional extension direction (Figs 1 and 2). Further south from the St-George-sur-Loire Synclinorium, the South Armorican shear zone (Fig. 1) is evidence for more intense shear. On the other hand, on moving north, within moderately deformed zones (such as the Sud de Rennes syndines, Fig. 1), the influence of a shear component becomes less apparent. Over large areas, we have not found any clear evidence for shearing during the main deformation, either from microtectonic criteria or fabric data<sup>8-10</sup>. Indeed, within this domain, the only clear evidences of shearing that has ever been reported is along the northern branch of the South Armorican shear zone<sup>6,17,18</sup> and also along discrete strike-slip microfaults in slates of the country-rocks<sup>9</sup>.

The overall geometry of the structures in Central Brittany (general trends of fold axes, cleavage trajectories and mapped shear zones; principal extension direction subhorizontal and parallel to fold axes) suggests the existence of large-scale dextral transcurrent shearing<sup>4,6</sup>. As shown above, regional strain gradients seem to be closely related to variations in intensity of shearing. Other evidence indicates that the ductile fault zones have acted as dextral strike-slip fault zones, not only in late Hercynian times, but also during the main Hercynian deformation, with associated local strain and metamorphism gradients<sup>6,14</sup>.

Fabric analysis and microtectonic analysis have not given any unequivocal evidence of non-coaxial deformation in weakly deformed zones. This kind of approach, though quite useful in sufficiently deformed rocks, seems to be less satisfactory for rocks exhibiting low strain intensities, where a stable fabric is not attained. Such investigations, if restricted to moderately deformed zones, can therefore lead to incorrect assumptions about the bulk deformation history. Thus, in the area under consideration, it gives only further evidence for regional short-

ening. Also, finite strain assessments which are locally significant cannot be directly extrapolated to provide a quantitative estimate of the geometry of the bulk strain (see ref. 25). In Central Brittany, perturbations induced by granitic bodies introduce further complications. Nevertheless, the overall low amplification of regional folds, bearing in mind that significant ductility contrasts exist between folded series<sup>9,10,21</sup>, is consistent with the observed principal extension subhorizontal and parallel to fold axes and with no evidence for important vertical finite extension. This pattern can be compared with results of bulk plane strain folding experiments<sup>26</sup>. In this way, deformation by shearing is thought to be the main factor limiting the vertical finite extension in Central Brittany.

An oblique convergence of a northern and a southern continental block might account for the observations and would be consistent with structural correlation that can be made between South and Central Brittany<sup>27</sup>. However, it remains difficult to estimate to what extent the bulk process may have differed from a regional simple shearing model. This might be overcome by extending detailed finite strain analysis throughout the whole region to complete the information about strain gradients and be able to calculate the effects of removing strains<sup>28,29</sup>. It has been suggested that the granites along the major shear zones could be the result of localized crustal melting by shear heating<sup>6,30</sup>. However, it has been thought that shear heating cannot in general be sufficient for this purpose<sup>31</sup>. Furthermore, the pattern of regional metamorphism is associated with a regional thermal anomaly which can account for the Hercynian plutonism<sup>3</sup>. The relation between major shear zones and granites can be explained by a thermally initiated strain softening in these zones<sup>32</sup>. Before the shear zones get sufficiently soft to allow most of the deformation to occur in these zones, it is reasonable to expect the entire region to deform as a whole. Regional Hercynian structures could, at least in part, be interpreted in this way. Then, dextral movements could continue along the main shear zones, up to late Hercynian times.

## Clays from New Zealand support the inactive particle theory of soil sensitivity

I. J. Smalley, Craig W. Ross & J. S. Whitton

Soil Bureau, Department of Scientific and Industrial Research, Lower Hutt, New Zealand

**As part of a long-term study of factors contributing to soil sensitivity, investigations have been carried out on some volcanic ash soils from the North Island of New Zealand. We report here that some soils have sensitivities of up to 140 and clay mineral contents of >80%. They apparently owe their high sensitivity to the fact that the clay is halloysite of the spherical variety, and that interparticle interactions with this particular soil mineral are remarkably slight. Although the clay soil has a high liquid limit (~65–80), it has a low plasticity index (~15–30) and its behaviour supports the inactive particle theory of soil sensitivity. When plotted on the Casagrande Plasticity Chart all samples plotted well below the 'A' line.**

Sensitivity is a measure of the loss in strength which occurs when a soil is disturbed or remoulded. In extreme cases the undisturbed soil strength can be several hundred times as great as the remoulded strength<sup>2</sup>. The ratio of undisturbed to remoulded strength indicates the sensitivity ( $S_t$ ). Soils of extremely high sensitivity (sometimes called quickclays:  $S_t > 50$ ) exist in eastern Canada and in Scandinavia and cause problems by landsliding and retrogressive flowslide behaviour. Various theories have been advanced to explain their properties: the role of interparticle cementation<sup>3</sup>, the leaching theory which has now evolved into a generalized electrochemical approach<sup>4</sup> and the inactive-particle, short-range-bond theory<sup>15</sup> are all being discussed. But choosing between the various approaches has been difficult because of the limited number of high sensitivity soils available. This situation has been helped by the discovery of soils with sensitivities reaching 140 in New Zealand. Initial investigations suggest that the cementation and Rosenqvist factors may not apply.

In August 1979 a damaging landslide occurred at Tauranga, on the northeastern fringe of the central volcanic plateau in the North Island of New Zealand. This landslide had many of the characteristics of a flowslide which occurs in highly sensitive soils and sensitivities of up to 140 were measured, although many much lower values were also recorded (C. Gulliver, personal communication). Mineralogical analyses by differential thermal analysis and X-ray diffraction (XRD) showed that the soil was largely composed (80%+) of hydrated halloysite (10 Å spacing on XRD); minor amounts of quartz and cristobalite were observed. At first sight this apparently contradicts the major requirement of the inactive particle theory, that the clay mineral content be small to negligible; however, the nature of the Tauranga halloysite is such that the observations and the requirements of theory can be reconciled. The inactive particle theory explains very high sensitivities by requiring that there be very little long-range attraction between the soil particles. In the Northern Hemisphere, this requirement is met by specifying that there should be very little active clay mineral content in the soil, and a recent programme of analyses on Canadian soils has shown that they do have low clay mineral contents<sup>6–8</sup>. But in New Zealand it is possible to find soils with a very high clay

mineral content which do not have the 'clayey' or high plasticity indices of soils of similar clay proportion encountered in Northern Hemisphere engineering soil investigations.

Scanning electron microscope studies (by G. Walker; see Fig. 1) show that the soil at Tauranga is composed essentially of spherical halloysite particles. The analytical results from scanning electron microscopy/electron diffraction by X-ray analysis (SEM/EDAX) show a  $\text{SiO}_2/\text{Al}_2\text{O}_3$  ratio of 1:1, which supports halloysite. Some small concretions were completely localized concentrations of iron and manganese (in roughly equal proportions); no sign of cementation was detected. These spherical clay particles (which are single crystalline units and not aggregations) form a very inactive clay with very small interaction with both positive and negative soil water ions; the phosphate uptake for a similar soil is the lowest measured in New Zealand<sup>9</sup>. Thus, although clay mineral particles predominate in the Tauranga material, long-range interparticle forces are essentially absent and the sensitivity is relatively high. The inactive particle theory will need to be generalized to require an absence of long range forces in the soil system rather than a lack of clay mineral materials, although investigations on a sensitive Norwegian soil<sup>11</sup> show that the minimum clay mineral requirement may still operate in the Northern Hemisphere.

Some structural collapse must be involved in the classic quickclay failure and yet the spherical particles might be expected to form a fairly compact structure. SEM reveals some variation in density with 'pores' distributed throughout the soil, and these seem to cause fairly low bulk densities, usually in the range 1.5–1.6 tonnes  $\text{m}^{-3}$ . Natural water contents of the sensitive ash soils were exceptionally high (60–100%) and were often above the liquid limits. The abundant water supports the separated particle once failure has occurred<sup>5</sup> but the initial brittle failure, leading to structural collapse, occurs because of a lack of long-range bonds in the system. Handy<sup>11</sup> has shown that structural collapse in the loess soils of Iowa is promoted by an absence of clay minerals and this observation could indirectly support the inactive particle sensitivity theory. Fedá<sup>12</sup> and Denisov<sup>13</sup> regard loess as a sensitive soil and relate its structural collapse on wetting to the total structural collapse exhibited by a quickclay when it is remoulded. In Iowan loess the primary mineral particles which form the basis of the soil structure are usually quartz with diameters of 20–60  $\mu\text{m}$ , in a Canadian quickclay the particles are quartz and feldspar and the diameters are around 2–5  $\mu\text{m}$  and in the New Zealand volcanic soil the

**Fig. 1** Spherical halloysite particles comprising the sensitive volcanic ash soil at Tauranga; each particle has a diameter of ~0.2  $\mu\text{m}$ . The particles are single crystalline units and not aggregates of smaller particles. (Photo: G. D. Walker, DSIR New Zealand.)

major soil particles are halloysite spheroids with diameters of  $\sim 0.2 \mu\text{m}$ ; they all seem to have a propensity for structural failure, and they all lack long-range forces. (But we have a few reservations about considering loess a truly sensitive soil.)

The existence of the Tauranga soil, with a sensitivity that puts it in the quickclay class (using the Swedish definition) and a remarkable mineralogy, offers the chance of taking another small step towards a general theory of sensitivity. It also supports the approach suggested in the inactive-particle, long-range-bond theory, and it might offer some common ground on which to reconcile the revised approach with the generalized Rosenqvist theory.

We thank Chris Gulliver for drawing our attention to the Tauranga slide and for supplying samples and engineering data.

## Formation of $\text{C}_4$ – $\text{C}_7$ hydrocarbons from bacterial degradation of naturally occurring terpenoids

John M. Hunt, Robert J. Miller & Jean K. Whelan

Woods Hole Oceanographic Institution, Woods Hole, Massachusetts 02543

**We have recently found many light hydrocarbons, both alkanes and alkenes, in trace amounts (ng compound per g sediment) in Recent marine sediments<sup>1–4</sup>. These hydrocarbons are believed to originate from both biological and low-temperature reactions in the sediments. Understanding their mechanism of formation may allow use of these compounds to decipher the past biological and thermal history of the sediments<sup>4</sup>. To investigate biological origins, we have cultivated mixed populations of bacteria on natural terpenoids and found, as degradation products, both alkanes and alkenes in the  $\text{C}_1$ – $\text{C}_7$  range; this is the first report of  $\text{C}_4$ – $\text{C}_7$  hydrocarbons being formed from microbial activities. Aerobic followed by anaerobic degradation yielded mainly small amounts of straight-chain alkenes. No such products resulted from blanks or controls. The results are consistent with products observed in natural environments.**

The analytical procedure was carried out in 125-ml glass bottles (Hungate method)<sup>5</sup> and 455-ml cans. Both types of vessels were equipped with silicone rubber septa<sup>2</sup> and shown to be gas tight by injecting a positive pressure of helium and testing with an electronic helium leak detector (Gow Mac).

All gases were passed through an alumina trap immersed in dry ice and an Oxisorb trap (Analabs) to remove traces of hydrocarbon or oxygen. All distilled water used in making solutions and media was sparged with helium for 5 min to remove any traces of volatile hydrocarbons. All anaerobic operations and transfers were carried out in a glove bag (12 R) which was alternately evacuated and filled three times with a mixture of 80%  $\text{N}_2$ –20%  $\text{CO}_2$  (the  $\text{CO}_2$  was Matheson, Anaerobe purity). Vessels were kept in the glove bag maintained with a slight positive pressure of 80%  $\text{N}_2$ –20%  $\text{CO}_2$  during bacterial growth to guard against accidental small leaks.

Media was artificial seawater<sup>6</sup> and other nutrients including Pfennig's<sup>7</sup> trace metal stock solution (1 ml per litre). About 30 ml of this media (sterilized and sparged with 20%  $\text{CO}_2$ –80%  $\text{N}_2$ ) containing 0.5–1.5 mg terpene in suspension (farnesol or  $\beta$ -

carotene) per ml medium were added to the sterilized cans and the cans sealed.

A mixed culture of anaerobic bacteria was collected from the sediments in a brackish water pond (Salt Pond) near our laboratory in a collection tube, which was evacuated and filled with an atmosphere of 80%  $\text{N}_2$ –20%  $\text{CO}_2$ . The sample was brought back to the laboratory and further operations were carried out in the glove bag described above. The material was filtered through a 1.2- $\mu\text{m}$  Millipore filter to exclude particulate matter and organisms larger than the desired bacteria. Portions of the filtrate (1 ml) were inoculated into sample cans containing media and farnesol or  $\beta$ -carotene as described above and blank cans which contained everything but the terpene (farnesol or  $\beta$ -carotene). Additional blank cans which had media and terpene substrates but no bacteria were also run with the other blanks. The cans were stored at room temperature and analysed as described below at the end of 144 h.

In the second method, the media was prepared in a device similar to that of Willingham<sup>7</sup>. The media (35 ml) (artificial seawater/Pfennig's solution as described previously plus 0.5 g per litre cysteine-HCl and a few drops of reazurin indicator solution dispensed into the serum bottles after  $\text{CO}_2$  was bubbled through the dispensing device so that the indicator turned from blue to red) was dispensed into the bottles which were subsequently sealed. Substrates and bacteria were added in the same concentrations as used in the cans. The bottles were kept at room temperature and analysed after 196 h. During this time, the reazurin indicator turned from pink to colourless indicating anoxic conditions. Several blanks were run, some using substrates and all carbon sources but no bacteria, others using bacteria and media as described above, but no terpene.

We also wanted to know whether aerobic bacterial metabolism could modify functional groups and make them more susceptible to anaerobic attack. About 4 g of a Noble bacto-agar (VWR) was dissolved by heating in 1 l of a mineral salts medium, autoclaved, cooled and divided into portions. Carbon sources (1.5 g yeast extract and 1.5 g tryptose per litre of medium) were added and several plates were filled with 20 ml of medium. The terpenoids (farnesol and  $\beta$ -carotene) were added initially in low concentrations (10% terpenoid carbon source, 90% yeast/tryptose) and concentrations were gradually increased to prevent inhibition of bacterial growth from too much terpenoid. The final carbon source was 90% terpenoid and 10% yeast extract/tryptose. High bacterial populations were observed by direct microscopic examination for 7 days at these concentrations. Culturing was terminated by dissolving the agar from each plate with concentrated (12 M) HCl (15 ml) and neutralizing with NaOH to pH 7. This solution was placed in the glove bag, sparged with 80%  $\text{N}_2$ –20%  $\text{CO}_2$ , and 30 ml added to the 125-ml Hungate bottles along with 20 ml of the reduced media described above. The bottles were sealed and anaerobic sediment inoculum were introduced into the samples as described previously. Blanks were run with everything but the bacteria and with everything but the terpenoids. Samples were maintained at room temperature and analysed after 210 h. Cultures were terminated by injecting 5 ml of 0.1 M  $\text{HgCl}_2$  into each bottle.

To drive all volatile compounds into the gas phase, the containers were heated at the end of the experiment in a hot water bath at 90°C for 15 min. An aliquot of the gas was withdrawn and analysed on a 200 ft  $\times$  0.01 inch i.d. stainless-steel hexadecane-hexadecene Kel F capillary (WCOT) column<sup>2</sup>. This column will separate most alkanes and alkenes in the  $\text{C}_4$ – $\text{C}_7$  hydrocarbon range as well as compounds with functional groups such as thio-ethers. Compounds were identified by retention time, by co-injection of standards and by gas chromatography-mass spectrometry. All of the compounds found in these experiments had previously been found in Recent sediments<sup>1–4</sup>. Limits of detection by this method are 0.003  $\mu\text{g}$  hydrocarbon per litre of medium.

The hydrocarbons formed in these experiments are listed in Table 1. None of these hydrocarbons was recovered in the blank runs including those with bacteria but no substrate and those

**Table 1** Yield of  $C_4$ – $C_7$  hydrocarbons from microbial degradation of terpenoids

† Detection limit 0.003  $\mu$ g per litre medium.

‡ Standard deviation from duplicate cultures.

with substrate but no bacteria. Small amounts of methane, ethane, propane and butane were found in some of the samples, but these were also in blanks that did not contain the terpenoids, so their presence was not considered a result of terpenoid degradation. Also, the samples run in the serum bottles with anaerobic bacteria, but no terpenoids, yielded 50  $\mu$ g per litre of dimethylsulphide and 25  $\mu$ g per litre of  $CS_2$  (detected by gas chromatography). When farnesol was added, these yields increased up to 60  $\mu$ g and 200  $\mu$ g per litre, respectively.

The most significant conclusion is that the anaerobic degradation process formed only a few specific hydrocarbons from each terpenoid. Only alkanes and toluene were formed in the metal cans, whereas alkenes were the main products in the glass serum bottles. The kinetics of alkene formation by the anaerobes is possibly faster than that of alkane formation, but is inhibited by the metal in the can. The formation of branched pentanes from either farnesol or  $\beta$ -carotene is conceivable through the breaking of a carbon-carbon bond in the beta position to the double bonds. It is more difficult to understand the formation of the toluene although methylcyclohexene might be a reasonable precursor<sup>4</sup>.  $\beta$ -Carotene will aromatize to form toluene when heated for 2 weeks at 119 °C (ref. 8). However, when heated at 90 °C for 15 min in the conditions of our experiments, no toluene was found within our detection limit (0.003  $\mu$ g per litre medium). The high yield of toluene in Table 1 only resulted when anaerobes were present in the can. The reason for formation of toluene in the cans but not in the bottles is unclear, but may be due to some effect of the metal in the can. Controls showing no toluene production were: (1) blanks having all substrates including carotene but no bacteria; and (2) bacteria with all carbon sources except carotene. Thus, toluene production due to a metal-catalysed chemical reaction has been ruled out. We did not do aerobic experiments with the metal cans so we cannot conclude that toluene forms exclusively in anaerobic environments.

The anaerobic culturing in the serum bottles yielded mainly branched alkenes. The experiments with aerobes followed by anaerobes yielded mainly straight-chain alkenes and one gem-dimethyl alkane, 2,2-dimethylbutane. The formation of this compound from  $\alpha$ -2-pinene could result from breaking off the 4-carbon ring with the quaternary carbon atom in  $\alpha$ -pinene.

The results of these preliminary microbial degradation experiments fit surprisingly well with our studies of hydrocarbon distributions in marine sediments. In the strongly reducing environment of Walvis Bay, we found that toluene constituted

70% of the  $C_4$ – $C_7$  hydrocarbons in the surface sediments<sup>4</sup>. The present laboratory experiments support the concept that toluene can be an anaerobic degradation product, and show that the gem-dimethyl alkanes, such as neopentane and 2,2-dimethylbutane dominate in sediments where the overlying waters (and topmost sediments) are oxidizing with deeper sediments reducing (Arabian Sea)<sup>3</sup>. These same environments also produced a diverse assemblage of alkenes, including straight-chain pentenes and hexenes. Such compounds seemed to arise from a combination of both aerobic and anaerobic microbial degradation of organic substrates, possibly together with low-temperature chemical reactions. Whelan *et al.*<sup>5</sup> have discussed in detail possible chemical reactions leading to the  $C_4$ – $C_7$  hydrocarbons, such as alcohol dehydration and allylic free radical cleavage. It has also been pointed out that bacterial reworking of algae forms an amorphous biomass high in bacterial bodies that is more readily converted to hydrocarbons in the  $C_{15}$  range<sup>9</sup>. However, we found no references to  $C_4$ – $C_7$  hydrocarbon formation by bacterial reworking.

We are not arguing that these products represent major metabolic paths in the organism. The trace amounts of substrate transformed suggest that these paths probably represent reactions which are incidental to the bacteria. However, the small (p.p.m.–p.p.b.) levels of compounds found in these experiments and in our Recent sediment analyses are comparable so that these microbial processes may explain one source of the compounds in Recent sediments. This is a valuable finding because the presence of a particular set of these molecules in more deeply buried cold sediments may provide information about the nature of the sediment-water interface (oxic or anoxic) when the sediment was buried in past geological time.

This work was supported by the Oceanography Section of the NSF grant OCE 79-19861. We thank Craig Taylor for critical evaluation, and Elizabeth McKenna and Marcia Pratt for culturing aerobes and analysing headspace gases. WHOI No. 4571.

## The principal eyes of a jumping spider have a telephoto component

David S. Williams &amp; Peter McIntyre

Department of Neurobiology, Research School of Biological Sciences, Australian National University, Canberra, Australia

Jumping spiders are a cosmopolitan family (Salticidae) of predators that can make visual discrimination between prey and mates<sup>1,2</sup>. This task is mediated through the anterior median eyes, described by Land<sup>3</sup> as consisting of a corneal lens and a mottle retina that comprises four layers of receptors embedded in a matrix. The retinal matrix contains a pit distal to the receptors and symmetrically centred on-axis. We have now found that in *Portia fimbriata* (Dolleschall) and some other species, this pit has a refracting interface that increases the focal length of the eye beyond its axial length, thereby magnifying the retinal image and increasing visual resolving power above that possible with only a corneal lens. The most effective part of the conical pit is its rounded apex, which augments the corneal lens to provide a telephoto system that increases the overall focal length by about 1½ times. This mechanism is of particular value to small spiders like *P. fimbriata*, for the possible axial length of their eyes is constrained by the small size of their prosomae (Fig. 1).

The inside of the pit of the anterior median eye of *P. fimbriata* is structureless and must have a refractive index ( $n$ ) close to that of saline, about 1.336 (Fig. 2). In glutaraldehyde-fixed material, cut while frozen, the matrix behind the pit was found by interferometry to have a uniform  $n$ , a value of  $\sim 1.40$  being obtained from unfixed material. The rounded apex of the pit is about  $20\text{ }\mu\text{m}$  in diameter; the most central region is approximately spherical, with radius of curvature  $\sim 5\text{ }\mu\text{m}$ , and thus acts as the diverging lens of the telephoto system (Fig. 3), with power  $(1.40-1.336)/(-5 \times 10^{-6}) = -12,800$  dioptres. In longitudinal profile, the rounded region is less curved beyond about  $4\text{ }\mu\text{m}$  from the axis and merges into straight sides (Fig. 2). Such an aspherical surface may well give a better image over a wider aperture than a spherical one. The curvature of the pit varies greatly among the different species of salticids and in some cases is so slight that the pit will have negligible power.

From a corneal lens (diameter  $810\text{ }\mu\text{m}$ ) of *P. fimbriata*, dissected out and hung from a drop of saline ( $n = 1.336$ ) to simulate *in situ* conditions<sup>4,5</sup>, a front focal length of  $-1,273\text{ }\mu\text{m}$ , that is, a power of  $+786$  dioptres, was measured (in green light, as was used for the measurements of  $n$ ). The second principal plane of the corneal lens was found nearly to coincide with the front surface of the lens, indicating that the air/cornea interface provides most of the refracting power. The remaining parameter necessary for determination of the optical properties of the telephoto system is the distance,  $d$ , between the corneal lens (more precisely, its second principal plane) and the pit.  $d$  was deduced from ophthalmoscopy, using an apparatus similar to that devised by Land<sup>3,6</sup>. By finding the position in space of the image of a recognizable part of the retina (in this case the virtual image of parts of the receptor cells in the characteristically organized fourth receptor layer, which on-axis lies  $25\text{ }\mu\text{m}$  behind the pit),  $d$  can be calculated from standard thick-lens formulae<sup>7</sup>. (Ideally the properties of the complete dioptric system could be determined directly from the magnification of the ophthalmoscopic image, but this was prevented by uncertainty about exactly which parts of the receptor cells in layer 4 provide the image.) The value determined for  $d$  ( $=1,664\text{ }\mu\text{m}$ ) is to be compared with the focal length in image space of the corneal lens ( $1,273 \times 1.336 = 1,701\text{ }\mu\text{m}$ ). To achieve a reasonable magnification without unduly increasing image distance, the pit must be a short distance inside the focal point of the corneal lens. This condition seems to be satisfied.

**Fig. 1** Diagrammatic horizontal section of the dorsal anterior part of the prosoma of *P. fimbriata*, showing the positions of the anterior (A) and posterior (P) median (M) and lateral (L) eyes. This eye-bearing portion of the prosoma projects dorsally. In the dorso-ventral plane, the posterior eyes lie just above the anterior median retinae.

**Fig. 2** Longitudinal section of an anterior median retina in *P. fimbriata* including part of one arm of its 'boomerang' structure. The material was fixed in glutaraldehyde and  $\text{OsO}_4$ , embedded in Araldite and stained with toluidine blue. Scale bar,  $50\text{ }\mu\text{m}$ . The interior of the pit (arrow) is structureless (the glass cells visible on the left side of the figure do not extend into the pit), but the surrounding retinal matrix has stained densely and homogeneously. Receptor layers are numbered. Horizontally, across the narrow centre of the retina, the distal ends of the layer 1 receptors are arranged as a staircase, such that on the lateral side of the retina they are  $25\text{ }\mu\text{m}$  more distal than on the medial. The overall radius of curvature of the retina in a dorso-ventral plane is far smaller than would be expected if the receptors were organized around the corneal lens. This indicates further that the retina is organized according to the combined properties of the corneal lens and the pit. Inset: Diagram outlining the two anterior median retinae in transverse section at the level of layer 1. The line indicates the plane of the longitudinal section.

Using the above parameters, the position of focus,  $F'$ , of the telephoto system for an object at infinity is  $59\text{ }\mu\text{m}$  behind the pit, corresponding to the distal on-axis region of the second receptor layer, and the magnification achieved by the pit lens is 1.54 (see Fig. 3). The following supports this finding. Comparative ultrastructural studies of salticid principal retinae<sup>8</sup> show that (1) layer 1 receptors in the central region form a high-resolution mosaic whose rhabdom organization implies that the individual rhabdoms are light guides; (2) layer 2 receptors form a coarse central mosaic with probable optical coupling between receptors. In *Plexippus*, recordings from dye-injected cells have identified both layers 1 and 2 as green receptors with peak responses at  $\sim 520\text{ nm}$  (ref. 9). Cells peaking in the green have also been found previously<sup>10</sup>; discrepancies between these results and other published data<sup>11</sup> will be discussed elsewhere<sup>9</sup>. Some salticids, including *P. fimbriata*, seem to discriminate between conspecifics and prey at distances of  $15\text{--}20\text{ cm}$  (refs 12, 13); *Trite planiceps* Simon, a salticid that we find has a significant pit, but lower overall image magnification than *P. fimbriata*, is known to make discriminations at distances of  $20\text{ cm}$  (ref. 12). Thus, a 'best solution' for the dioptric system must provide focused images of objects,  $\sim 20\text{ cm}$  in front of the spider, at the tips of the rhabdoms of layer 1, when  $\lambda = 520\text{ nm}$ . For  $F'$  near the distal ends of the layer 2 receptors, the distal ends of those of layer 1 (Fig. 2) receive best images from objects  $15\text{--}29\text{ cm}$  in front of the spider and have a total depth of field of  $9\text{ cm}$  to  $\infty$ . The depth of field is estimated by compounding the horizontal 'staircase' tiering of the distal ends of layer 1 receptors (which gives the  $15\text{--}29\text{-cm}$  range) with the depth of focus due to diffraction at the aperture of the eye<sup>7</sup> (see below).

The retina of an anterior median eye is boomerang-shaped (Fig. 2), measuring only  $250\text{ }\mu\text{m}$  dorso-ventrally and  $25\text{ }\mu\text{m}$  wide—a size reduction necessary to accommodate the eye's long axis<sup>3</sup> (Fig. 1). At the level of layer 1, the receptors in the centre of

Fig. 3 General schematic illustration of the enlargement of an image by the diverging back element of a telephoto system. o, object; i, image; i', image in absence of diverging surface. The magnification,  $m$ , effected by the pit lens in *P. fimbriata* is given by<sup>7</sup>

$$m = \frac{\text{size of } i}{\text{size of } i'} = P_L/P_T = \left[1 + \frac{P_P(1 - \bar{d}P_L)}{P_L}\right]^{-1}$$

where  $P_T$  is the power of the telephoto lens system, and  $P_L$ ,  $P_P$  the powers of its components, the converging corneal lens and the diverging pit lens respectively  $\bar{d} = d/1.336$ , with  $d$  as defined in the text. This magnification requires an increase in the axial length of the eye of only 22  $\mu\text{m}$

the retina have oval transverse profiles (minimum size 0.8  $\mu\text{m} \times 1.5 \mu\text{m}$ ) and form an hexagonal array with a minimum receptor-row spacing of 1.4  $\mu\text{m}$  (ref. 8), corresponding to a visual angle of 2.4 arc min. (This corresponds to a distance of 0.12 mm at 20 cm in front of the spider.) The resolving ability of a receptor mosaic depends on the angular subtense between neighbouring receptors, that is, on the receptor spacing and focal length of the eye. The receptor spacing at the centre of layer 1 is near the limit imposed by the wave nature of light, because optical crosstalk<sup>14</sup> between the 80–100- $\mu\text{m}$  long rhabdoms would probably be excessive were they much closer together. Therefore, the only way to enhance the anatomical resolving power of the eye is to increase its focal length. Image magnification by the pit achieves this, albeit at the cost of narrowing the field of view of the central retina. About 100 receptors in the centre of layer 1 lie behind the curved region of the pit in a circle of diameter 21  $\mu\text{m}$ —most of the width of the central part of layer 1. In total they have a field of view of 0.6°.

Vertically, the field of view of the eye is extended by the dorsal and ventral extremities of the retina. Light reaching these regions must pass through the sides of the pit which, in longitudinal section, are straight beyond 10  $\mu\text{m}$  from the optic axis and inclined at 30° to it. They produce a range of magnifications of 1.1–1.25, depending on the angle at which rays are incident. Magnification by the whole pit is therefore greatest on-axis, owing to the lens component, and decreases to a negligible amount for very off-axis light. Because off-axis magnification is different for different angles of incidence on the sides of the pit, off-axis focus will be blurred. This poorer image quality is reflected by the receptor mosaic off-axis in layers 1 and 2 where the rhabdoms are larger (~10  $\mu\text{m}$  in diameter) and practically contiguous.

A jumping spider's field of view is extended horizontally by its lateral eyes which, in conjunction with the vertical extremities of the anterior median retinae, allow peripheral detection. Peripheral detection of an object initiates body and anterior median retinal movements that bring images of the object to lie in the centres of the retinae and maintain them there during fixation<sup>6</sup>.

Land<sup>3</sup> suggested that the resolution of the anterior median eyes of two salticid species is probably limited by spherical aberration of their corneal lenses. Our re-examination of the lenses of *P. fimbriata* and several other salticids in a hanging drop and by interference microscopy shows that this defect is corrected by a graded refractive-index distribution in the lens, as in some nocturnal spiders<sup>5,15,16</sup>. Probably, then, the anterior median corneal lenses in salticids are diffraction limited. If this is true of the telephoto system of *P. fimbriata* as a whole, the

maximum or cut-off spatial frequency passed by it is 760  $\text{rad}^{-1}$  (refs 17–19). (The limiting aperture is a ring of pigment, 350  $\mu\text{m}$  in diameter and 315  $\mu\text{m}$  behind the corneal surface. The position of focus is taken as the distal ends of the receptors in layer 1.  $\lambda = 520 \mu\text{m}$ .) The highest spatial frequency that can be reconstructed by layer 1 with minimum receptor-row spacing 1.4  $\mu\text{m}$  and distance 1,980  $\mu\text{m}$  from the posterior nodal point of the telephoto system is  $1,980/2.8 = 710 \text{ rad}^{-1}$ . Therefore, the receptor spacing in the centre of layer 1 seems to be well matched to the telephoto system. In the absence of the pit, the highest frequency reconstructable by the retina would be only 420  $\text{rad}^{-1}$ , which is well below the cut-off frequency for the lens of 850  $\text{rad}^{-1}$ .

A parallel to the pit of *P. fimbriata* is the deep convexiculate fovea found in some vertebrates, notably falconiform birds<sup>20</sup>. It has been proposed that this fovea magnifies the retinal image<sup>20,21</sup> and acts as a focus indicator<sup>22</sup>. The latter is an implausible function for the pit in *P. fimbriata*, for as in other salticids<sup>3</sup>, ophthalmoscopy shows that the eye does not accommodate. Aerodynamic constraints require the heads of birds to be small. Both a group of vertebrates and an invertebrate have therefore adopted the same strategy to improve visual acuity despite a restricted cephalic space.

We thank Robert Jackson for collecting *P. fimbriata* from Queensland, Fred Wanless (British Museum) for identifying them, and David Blest for his critical comments, for providing much anatomical information and for obtaining *Trite planiceps* in New Zealand with the help of Simon Pollard and Robert Jackson. Part of this report has been published elsewhere<sup>23</sup>.

## Correlative genetic variation in natural populations of cats, mice and men

Stephen J. O'Brien,\* Mitchell H. Gall† & David L. Levin†

\*Laboratory of Viral Carcinogenesis, National Cancer Institute, National Institute of Health—Frederick Cancer Research Center, Frederick, Maryland 21701

†Biometry Branch, National Cancer Institute, National Institutes of Health, Bethesda, Maryland 20205

The study of the extent and basis of gene-enzyme variation has long been a principal concern of population genetics. Numerous surveys have indicated considerable amounts of genetic variation detectable in natural populations, with few exceptions<sup>1–14</sup>. The variances of average heterozygosities ( $H$ ) between species and among populations within species are large, prompting Lewontin to emphasize the importance of large gene sample sizes<sup>7</sup> and Selander to encourage analysis of variation of

homologous gene-enzyme systems when making species comparisons<sup>8</sup>. We present here a comparative genetic analysis of electrophoretic variation at 57 homologous biochemical loci of cats, mice and men. The distribution of polymorphism among the sampled loci in the three species was nonrandom. A large group of sampled loci (60%) were monomorphic in all three species, whereas a second group (30%) of the loci were polymorphic in two or more species. This conservation of the tolerance of genetic polymorphism is apparently more a characteristic of a particular locus than of the vertebrate species or of the genome. The current hypotheses for classifying polymorphic and monomorphic loci in terms of physiological and physical enzyme characteristics have been re-examined.

Table 1 shows a list of per locus heterozygosities ( $h = 1 - \sum x_i^2$ , where  $x_i$  is the frequency of the  $i$ th allele at a locus) of 57 gene-enzyme systems of one feline, two murine and two human populations. The loci encode homologous enzymes of the species, based on enzymatic, histological and molecular enzyme characteristics<sup>6,15-17</sup> as defined elsewhere<sup>15</sup>. The nomenclature of the human and feline loci conforms to the recommendations given in ref. 18; similarly the mouse nomenclature conforms to recommendations of ref. 19. The 57 loci are those which have been studied in either the cat population<sup>6</sup> or the two mouse populations<sup>10</sup>, and also in human populations<sup>2,20</sup> and for which enzymatic homology has been tentatively established. The feline population is a feral farm cat population studied at 55 loci<sup>6</sup>. The human data are from Harris<sup>20</sup> in almost all cases and represent cumulative estimates summarized by Harris and Hopkinson<sup>2,15</sup>. These estimates of human loci agree well with those presented by Nei and Roychoudhury<sup>21</sup>. In a few cases (*GALA* and *ALB*) the latter estimates are used because these loci are not included by Harris and Hopkinson<sup>2,15,20</sup>.

The LC and BC mouse populations are feral mouse populations collected in Southern California in 1977 and have been described in detail elsewhere<sup>10,22</sup>. To demonstrate that these are representative mouse populations, they were compared with previous surveys, that is, those of the island east of Jutland, Denmark population<sup>5</sup>; the Hallowell Farm, California population<sup>4</sup>; the British mainland population<sup>23</sup>, and the outbred Swiss mouse colony at the Eppeley Institute, Omaha, Nebraska<sup>24</sup>. The 12 polymorphic mouse loci in LC and/or BC listed in Table 1 were all polymorphic in previous mouse surveys. Four of the murine loci *Es-10*, *Glo-1*, *Mod-2*, and *Gpd-1* that are monomorphic in LC and BC, but fall in the polymorphic cluster (1-22 in Table 1), are also polymorphic in other mouse surveys<sup>4,5,23-25</sup>.

The 57 loci in Table 1 are listed according to the extent of polymorphism seen in the three species. The first 22 loci are polymorphic in at least 1 of the 3 species, and, of these, 14 (25% of the total) are polymorphic in 2 species. The estimate rises to 30% if *Glo-1*, *Mod-2*, *Es-10* and *Gpd-1* (which are monomorphic in LC and BC mice but vary between inbred strains and in Swiss, Hallowell Farm and Jutland Island mice) are included. If the distribution of allozyme polymorphism in two species were independent, the frequency of systems which are polymorphic in any two species would be equal to the product of their individual polymorphism frequencies. For example, in our cat sample<sup>6</sup> (Table 1), the proportion of loci tested which were polymorphic ( $P_{cat}$ ) was 0.22 (12/55 loci). The value for the California mice ( $P_{mouse}$ ) sampled was 0.20. Thus, the expected frequency of loci which are polymorphic in both species, if the estimates were independent, equals  $P_{cat} \times P_{mouse} = 0.04$ . The observed frequency of systems which vary in both cat and mouse was 0.14 (5 of 35 loci), nearly 4 times greater than expected.

Table 1 Comparison of biochemical allelic variation of homologous loci of cat, mouse and man

| Human/feline gene | Homologous mouse gene | Subunit number | Subunit molecular weight ( $\times 10^{-3}$ ) | Enzyme class | h = heterozygosity                   |                     |         |                               |      |
|-------------------|-----------------------|----------------|---|--------------|--------------------------------------|---------------------|---------|-------------------------------|------|

Enzyme homology (first 2 columns) is based on the following characteristics: (1) substrate specificity; (2) tissue distribution; (3) subcellular organelle association; (4) formation of heteropolymer in somatic cell hybrids; (5) cofactor affinity, and (6) relative electrophoretic mobility. The specific characteristics of each system are described elsewhere<sup>6,15-17</sup>. Subunit number and molecular weight estimates were obtained from refs 39 and 40. Enzyme class after the definitions of Johnson<sup>32</sup>. V, variable substrate class; R, regulatory enzyme class; N, non-regulatory enzyme class. Heterozygosity ( $h$ ) at each locus (assuming Hardy-Weinberg equilibrium) =  $1 - \sum x_i^2$  where  $x_i$  is the frequency of the  $i$ th allele in the population at the locus. A locus is considered to be polymorphic if  $h \geq 0.05$ . If two  $h$  measurements are available, as for LC and BC mice, the species is said to be polymorphic at that locus if either  $h$  value equals or exceeds 0.05. The data are derived from published surveys of feline<sup>6</sup>, human<sup>2,20</sup>, and murine<sup>10</sup> populations. To test for nonrandom distribution of polymorphic loci in the three species sampled, consider only those ( $T = 34$ ) loci for which complete data are available. If  $P_c$ ,  $P_h$ , and  $P_m$  are the numbers of polymorphic loci in the cat, human and murine samples, and  $M_c$ ,  $M_h$  and  $M_m$  are the corresponding numbers of monomorphic loci, then, under independence, the expected number of loci polymorphic in all species ( $PPP$ ) is  $(P_c/T)(P_h/T)(P_m/T)T = 0.7872$  and the expected number of loci monomorphic in all three species ( $MMM$ ) is  $(M_c/T)(M_h/T)(M_m/T)T = 11.7716$ . The expected number of concordant loci ( $PPP + MMM$ ) is 12.5588. The observed value is  $2 + 17 = 19$  concordant loci. The values  $P_c = 7$ ,  $P_h = 13$ ,  $P_m = 10$ ,  $M_c = 27$ ,  $M_h = 21$  and  $M_m = 24$  were obtained from Table 1 using the definition of monomorphic  $h < 0.05$  given above. To determine whether the observed number of concordant  $PPP$  matches ( $Y_1$ ) and concordant  $MMM$  matches ( $Y_2$ ) were significantly greater than expectation, the joint distribution of  $Y_1$  and  $Y_2$  was computed. The number  $X$  of  $PP$  matches for cat and mouse has the hypergeometric mass function  $P(X) = C(P_c, X)C(M_c, P_m - X)/C(T, P_m)$  where  $T = P_c + M_c$  and  $C(n, x) = n!/(x!(n-x)!)$ . Possible values of  $X$  are determined from the  $2 \times 2$  table with margins  $P_c$ ,  $M_c$  and  $P_m$ ,  $M_m$ . Given  $X$ , the conditional joint distribution of  $Y_1$  and  $Y_2$  is given by  $P(Y_1, Y_2|X) = C(X, Y_1)C(b, Y_2)/C(d, P_h - Y_1 + Y_2 - b)/C(T, P_h)$  where  $b = T + X - P_c - P_m$  and  $d = P_c + P_m - 2X$ . Possible values of  $Y_1$  and  $Y_2$  are determined, given  $X$ , from the  $2 \times 3$  table with margins  $X$ ,  $b$ ,  $d$  and  $P_h$ ,  $M_h$ . The joint probability mass function  $P(Y_1, Y_2)$  is obtained for each  $Y_1$  and  $Y_2$  as the sum over all possible  $X$  of terms  $P(X)P(Y_1, Y_2|X)$ . From this distribution it follows that  $P(Y_1 \geq 2) = 0.17410$ ,  $P(Y_2 \geq 17) = 0.00106$  and  $P(Y_1 + Y_2 \geq 19) = 0.00396$ . Thus the number ( $Y_1$ ) of concordant  $PPP$  is not significantly in excess of expectation, but the numbers of  $MMM$  ( $Y_2$ ) and total ( $Y_1 + Y_2$ ) concordances are significantly greater than predicted by chance. To check these calculations, exact means, variances, and covariances of  $Y_1$  and  $Y_2$  were computed using indicator functions and found to agree with those moments of the distribution  $P(Y_1, Y_2)$ . These moment calculations extend the two-dimensional analysis of Everitt<sup>41</sup> to three or more dimensions. In addition, simulation studies confirmed the calculations of  $P(Y_1 \geq 2)$ ,  $P(Y_2 \geq 17)$  and  $P(Y_1 + Y_2 \geq 19)$  above. If the definition of monomorphic is changed from the widely used value  $h < 0.05$  to the very stringent value  $h < 0.01$ , the number of  $MMM$  concordances is reduced to  $Y_2 = 13$  whereas  $Y_1$  is unchanged. Using the corresponding parameters  $P_c = 7$ ,  $M_c = 27$ ,  $P_h = 17$ ,  $M_h = 17$ ,  $P_m = 10$ ,  $M_m = 24$ , we find  $P(Y_1 \geq 2) = 0.2716$ ,  $P(Y_2 \geq 13) = 0.02627$  and  $P(Y_1 + Y_2 \geq 15) = 0.03586$ . Thus, even with this unusually stringent definition of monomorphic, the excess in  $Y_2$  and  $Y_1 + Y_2$  is statistically significant.

\* Indicates those enzyme systems which are inter-locus heteropolymers.

A similar comparison of cat and human<sup>2,6,20</sup> gave an expected overlap frequency of  $P_{cat} \times P_{human} = 0.22 \times 0.28 = 0.06$ ; the observed frequency (Table 1) was  $7/46 = 0.15$ . The mouse-human expectation was 0.06, and the observed match frequency 0.15. The expected frequency of systems polymorphic in all three species assuming random distribution was  $P_c \times P_h \times P_m = 0.01$ . The actual frequency of triple matches was 2 in 36 (0.06). The frequency of polymorphic triplets may actually be higher than indicated because four mouse loci, whose homologues are polymorphic in cat and man, are likely to be polymorphic in mouse, but were not considered as such in our analysis. *Es-10* and *Gpd-1* vary between inbred strains, presumably reflecting allelic variation in their founders<sup>25</sup>. Human and feline *PGM3* have no murine counterpart, although *PGM3* is polymorphic in man, cats and dogs<sup>2,6,26</sup>. *FUCA* is polymorphic in cat and man, but has not yet been typed in any murine population. A three-dimensional statistical analysis of the distribution of polymorphic against monomorphic loci in Table 1 revealed a

significant ( $P = 0.004$ ) excess of monomorphic triplets (that is, loci monomorphic in each species) and polymorphic triplets (loci polymorphic in all three species) over expectation. The statistical methods are shown in Table 1 legend.

The interspecies correlation of the loci which are polymorphic and those which are monomorphic emphasizes the notion that genic polymorphism is a characteristic of certain homologous loci, but not of others in these different species, which have been isolated in evolutionary time for 80 Myr. Certain loci, then, seem to have an adaptive tolerance to accommodate genetic variation whereas others do not, presumably due to selective constraints which physiologically or functionally restrict significant introduction of gene-enzyme variants into a population. An extension of this situation would be the possibility of selective advantage in polymorphism *per se* at the variant loci themselves, in a situation similar to the major histocompatibility complex (MHC) of all vertebrates thus far studied<sup>27,28</sup>. The MHC loci are characteristically polymorphic in natural popu-

lations, often with dozens of segregating alleles rendering virtually 100% heterozygosity within the population.

The molecular and physiological basis of the tendency of specific loci to be polymorphic (or not) is not immediately apparent. A number of adaptive and metabolic models have been proposed to be operative in this decision in *Drosophila* and human populations<sup>29-34</sup>. Enzyme characteristics which have been suggested in this determination include: (1) whether an enzyme has broad substrate specificity and uses exogenous environmental substrates compared with enzymes with narrow substrate specificities and which are members of intermediary enzyme pathways<sup>29-31</sup>; (2) whether or not an enzyme in a pathway exerts a regulatory role<sup>32,33</sup>; (3) the structural gene size as estimated by subunit molecular weight<sup>34,35</sup>; and (4) selective neutrality of the sub-genic portions of polymorphic genes which vary by random mutational substitution<sup>36</sup>. We have estimated the amount of variation in *h* values which can be explained by the first three selective hypotheses using a one-way analysis of variance (data not shown). Although there are tendencies in each case to conform to the models, in no case can more than 10% of the variation be explained by any one model. Whether selective or non-selective factors contribute inordinately to allozyme variation of these systems is not clear.

Finally, the evolutionary conservation of genetic organization and selective factors has also been observed between these three classes of organisms in comparative genetic mapping<sup>16,37,38</sup>. Apparently, blocks of genes have been conserved as linkage groups in a number of cases between cats, mouse and man<sup>16,17,37,38</sup>. The comparative linkage associations and the comparative population structures of these distantly related mammalian genera provide hope for the further understanding of adaptive processes of chromosomal and molecular evolution.

We thank Drs Bruce Grant, Harry Harris, George Johnson and Ross MacIntyre for their discussions during these studies.

## Delayed formation of proteoglycan aggregate structures in human articular cartilage disease states

T. R. Oegema Jr

Departments of Orthopaedic Surgery and Biochemistry, University of Minnesota, Minneapolis, Minnesota 55455

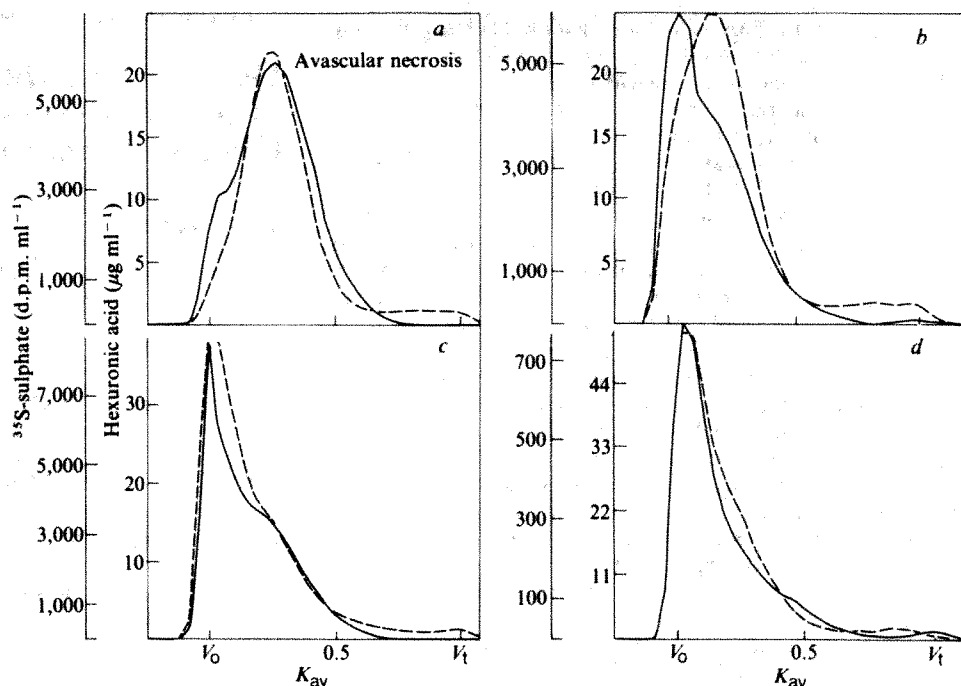

Proteoglycans are major components of many extracellular matrices. In cartilage, they provide reversible resistance to compression and exist as molecules with molecular weights (MWs) of  $1-3 \times 10^6$ . There is a central protein core of MWs approximately  $2 \times 10^5$  (refs 1, 2) with specialized subregions, one containing mainly the chondroitin sulphate chains<sup>3</sup>, another most of the keratan sulphate chains<sup>4</sup>, and a third is a largely globular structure interacting specifically with both hyaluronic acid<sup>5</sup> and a link protein<sup>6</sup> to form stable aggregate structures such as those identified in human articular cartilage<sup>7</sup>. In embryonic<sup>8</sup> and tissue culture systems<sup>9</sup>, proteoglycans are isolated as aggregate structures in as little as 5-10 min after synthesis (sulphation) with no nonaggregating precursor detected. However, Heinegård and Hascall have characterized the small proportion of nonaggregating proteoglycan present in bovine nasal septum cartilage and found that it contained more peptide than the aggregating proteoglycan<sup>10</sup>. Work by Upholt *et al.*<sup>11</sup> has suggested that the MW of unprocessed protein core, synthesized by a wheat-germ translating system from chick sternal cartilage mRNA, is ~340,000, leaving open the possibility of intermediates. I report here the presence, in some human cartilages, of a proteoglycan population that initially will not aggregate with the hyaluronic acid but subsequently can be chased into aggregate.

Human articular cartilage samples were obtained as described previously<sup>12</sup> from normal femoral heads and osteoarthritic joints in the areas immediately adjacent to the osteoarthritic lesion and from kidney-transplant patients undergoing total hip arthroplasty for steroid-induced avascular necrosis. Samples were labelled *in vitro* in RPMI 1640 media as described previously (<sup>35</sup>S-sulphate concentration of 100  $\mu$ Ci ml<sup>-1</sup>) for 4 h (ref. 13) and then part of the sample was extracted with 4 M guanidine hydrochloride in the presence of protease inhibitors<sup>2</sup>. The remainder of the sample was transferred to nonradioactive media containing 0.5 mM sulphate, chased for 18 h, and subsequently extracted as the 4-h samples. The proteoglycan monomer was purified from the extract by a dissociative caesium chloride density-gradient procedure<sup>2</sup>. The proteoglycans were isolated in the bottom two-fifths or D1 fraction and were subsequently examined for incorporated isotope and the ability to interact with hyaluronic acid<sup>2</sup>. The extracted residue was examined for nonextracted, incorporated isotope as described previously<sup>13</sup>.

Results indicated that both 4-h pulse and 18-h chase samples had the same total incorporation, so there was no incorporation of isotope during the chase period. Ninety-five per cent of the incorporated isotope was found in the bottom D1 or proteoglycan monomer fraction. The per cent extractable which varied from cartilage to cartilage (between 38 and 65%) was not different for the paired 4- and 18-h samples, indicating no significant change in the extractable pool size. There were three classes of response: <sup>35</sup>S-sulphate-labelled proteoglycan from normal cartilage ( $n = 2$ ) interacted with hyaluronic acid to the same extent at both 4 and 18 h (60-70%). Proteoglycans from patients with avascular necrosis ( $n = 3$ ) consistently would not interact with hyaluronic acid at 4 h but would interact at 18 h (Fig. 1b, c) with two additional samples having partial response at 4 h. The osteoarthritic cartilage ( $n = 5$ ) gave intermediate

**Fig. 1** The elution profiles for rat chondrosarcoma carrier proteoglycan hexuronic acid (—) and  $^{35}\text{S}$ -sulphate (---) from sepharose CL-2B for  $^{35}\text{S}$ -sulphate-labelled proteoglycans isolated from avascular necrotic human articular cartilage. *a*, 4-h incubation sample with no added hyaluronic acid. *b*, 4-h incubation sample plus 4% (w/w) added hyaluronic acid. *c*, 18-h chase sample plus 4% added hyaluronic acid. *d*, Proteoglycan reisolated after tumour treatment plus 4% hyaluronic acid. For the 4-h sample, the D1-2 fraction contained  $2.37 \times 10^6$  d.p.m. and represented 89% of the extracted d.p.m. and 46.7% of the total incorporated  $^{35}\text{S}$ -sulphate. The 18-h chase D1-2 fraction contained  $2.2 \times 10^6$  d.p.m. and represented 90% of the extracted d.p.m. and 50.8% of the total incorporated  $^{35}\text{S}$ -sulphate. Of the tumour-treated D1-2 fraction, 97% of the incorporated  $^{35}\text{S}$ -sulphate was in the D1-2 or bottom gradient fraction after the treatment, and 90% of the initially added isotope was recovered. The 18-h and tumour-treated controls with no added hyaluronic acid were identical to the 4-h control with no added hyaluronic acid. Carrier (2 mg) was added for each chromatographic run. The proteoglycan extracted from the tissue represented less than 5% of this value. The incubation with the chondrosarcoma included 0.5 g of freely isolated tumour that was finely minced and briefly washed with RPMI 1640 medium. The tumour was incubated for 4 h at 37 °C in 95% air–5%  $\text{CO}_2$  with the labelled proteoglycan that had been dialysed into (3 ml) RPMI 1640. In controls, similarly treated labelled proteoglycans from the chondrosarcoma were recovered unchanged in these incubation conditions. The presence of 10% heat-inactivated fetal calf serum did not alter the results.

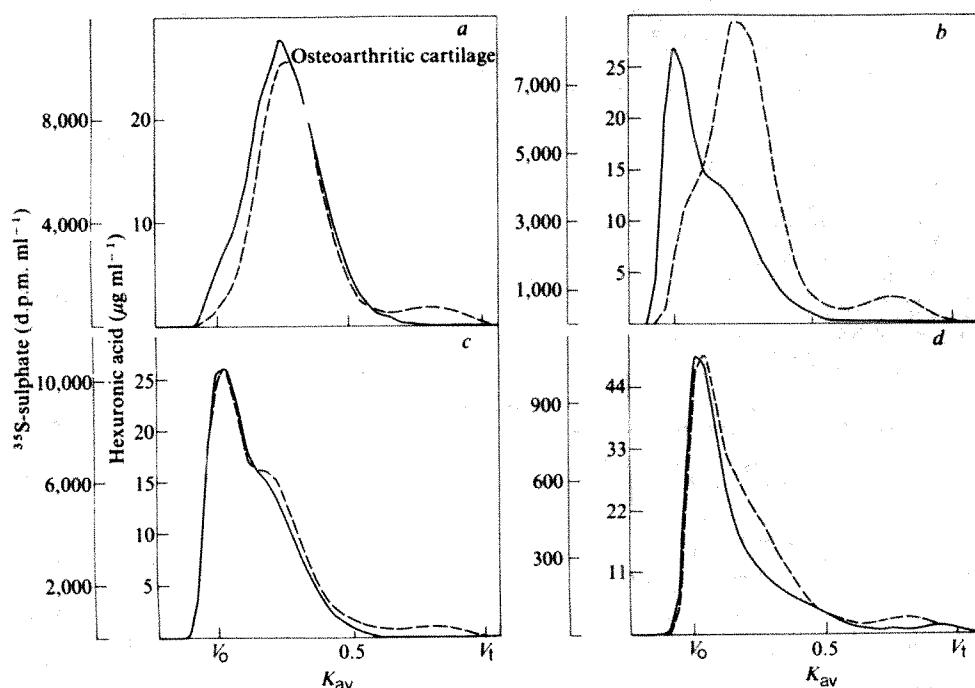

responses with some of the tissues, being unreactive at 4 h (Fig. 2*b*) and 70–80% reactive at 18 h (Fig. 2*c*). In some tissues, the proteoglycans were reactive to the extent of 20–30% at 4 h and were completely (60–70%) reactive at 18 h. When isolated  $^{35}\text{S}$ -sulphate-labelled proteoglycan samples that were non-interactive at 4 h, were treated in the presence of a mince of rat chondrosarcoma<sup>2</sup> for 4 h, reisolated into a dissociative gradient and re-treated with hyaluronic acid, the samples then formed 60–70% aggregate (Figs 1*d*, 2*d*). Controls, in which the tumour was boiled before incubation, showed no conversion to a

hyaluronic interactive form, suggesting a required heat-labile component for conversion.

I therefore suggest that there is a delayed conversion from a hyaluronate-noninteractive precursor to a form that can interact with hyaluronic acid in some osteoarthritic and avascular human cartilages. At present, there is no evidence that this is a classical conversion of a proform to an interactive form or whether there may be a subtle alteration in the structure, such as the slow formation of the correct disulphide bonds in these disease-affected human cartilages. Furthermore, these results may be of

**Fig. 2** The elution profiles for rat chondrosarcoma carrier hexuronic acid (—) and  $^{35}\text{S}$ -sulphate (---) from Sepharose CL-2B for samples of proteoglycans isolated from osteoarthritic cartilage. *a*, 4-h incubation sample with no added hyaluronic acid. *b*, 4-h incubation sample plus 4% (w/w) added hyaluronic acid. *c*, 18-h chase sample plus 4% hyaluronic acid. *d*, Proteoglycan reisolated after treatment with chondrosarcoma plus 4% hyaluronic acid. For the 4-h sample, the D1-2 fraction contained  $1.79 \times 10^6$  d.p.m. and represented 87% of the extracted d.p.m. and 53% of the total incorporated isotope. The 18-h chase D1-2 fraction contained  $1.89 \times 10^6$  d.p.m. and represented 90% of the extracted d.p.m. and 69% of the total incorporated isotope. Of the tumour-treated D1-2 fraction, 97% of the  $^{35}\text{S}$ -sulphate incorporation was in the D1-2 or bottom gradient fraction after the treatment and over 90% of the initially added isotope was recovered. The 18-h and tumour-treated controls with no added hyaluronic acid were identical to the 4-h control with no added hyaluronic acid.

more general application, as the hyaluronic acid-dependent proteoglycan aggregate has recently been reported in other systems<sup>13,14</sup>.

## Use of aequorin to study excitation-contraction coupling in mammalian smooth muscle

Ian R. Neering\* & Kathleen G. Morgan

Departments of Pharmacology and Physiology and Biophysics, Mayo Foundation, Rochester, Minnesota 55901

Considerable information is available for intact skeletal and cardiac muscle cells on the role of changes in intracellular  $\text{Ca}^{2+}$  ( $[\text{Ca}_i^{2+}]$ ) levels during excitation-contraction coupling<sup>1–3</sup>.  $\text{Ca}_i^{2+}$  levels seem to be similarly important in smooth muscle<sup>4,5</sup>. However, only two published reports describe the use of indicators to directly measure  $[\text{Ca}_i^{2+}]$  in intact smooth muscle cells. One described the use of murexide in molluscan smooth muscle<sup>6</sup>, the other the use of aequorin in single amphibian cells<sup>7</sup>. Their results differed: very long calcium transients were described for the molluscan muscle, compared with very brief ones for the amphibian cells. We present here the first description of the relationship between calcium transients and contraction of whole, mammalian smooth muscle injected with aequorin. The  $\text{Ca}^{2+}$  transient we observed has a slow rise, a long duration, and there was no delay between the peak of the  $\text{Ca}^{2+}$  transient and the onset of force. This contrasts with the amphibian findings but resembles the molluscan data. We observed a delay between the onset of the increase in  $[\text{Ca}_i^{2+}]$  and the onset of the rise in tension which might be explained, at least in part, by the presence of a threshold  $[\text{Ca}_i^{2+}]$  for concentration.

Strips of dog antral circular smooth muscle were prepared as described previously<sup>8</sup>. In each preparation aequorin<sup>9,10</sup>, dissolved in 150 mM KCl, 5 mM HEPES, pH 8.0, was pressure-injected through glass micropipettes into 20–60 cells over an approximately 1-mm<sup>2</sup> area. Light from the aequorin-injected area was detected with an EM1 9635A photomultiplier tube<sup>1</sup>. Figure 1a shows simultaneously recorded light and tension signals in the preparation which gave the largest light response. Both light and tension transients were reproducibly recorded in excess of 128 responses occurring over more than 2 h. This indicates that significant consumption of aequorin was not occurring over this time period. Figure 1b, c shows averaged signals giving a clearer indication of the relationship between light and tension. The onset of the stimulus was coincident with an immediate rapid increase of luminescence (Fig. 1c,

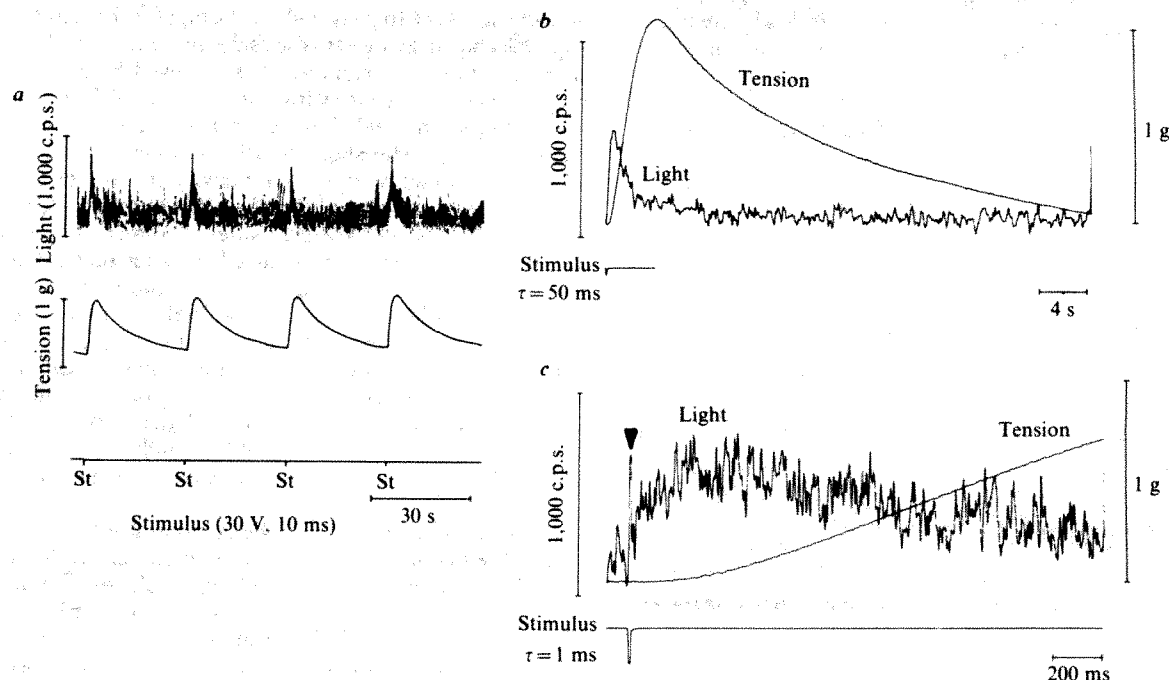

arrowhead) (time to peak 3–4 ms) lasting for the duration of the stimulus and decaying with the same time course as the rise. The short-duration light response was followed by a much slower increase in luminescence with a time to peak of 200 ms (range in five preparations 200–800 ms) and a half decay time of 2 s (range 2–2.5 s). The short-duration response was particularly sensitive to stimulus intensity. At low intensities it was virtually absent, whereas at high intensities light saturated the recording system. At the same, low intensities, the longer-duration light signal and the contraction persisted and an actual potential was still triggered. We think that the short-duration light signal is probably associated with an abnormal membrane response, which has been postulated to explain similar transients in amphibian smooth muscle<sup>7</sup>. Action potentials in canine gastric smooth muscle are often 10 s in duration and seem to involve a  $\text{Ca}^{2+}$  current<sup>8</sup>. Thus, a component of the slower light ( $\text{Ca}^{2+}$ ) transient may occur as a result of  $\text{Ca}^{2+}$  influx during the action potential; however, intracellular release of calcium may also be involved.

It is interesting to compare the responses obtained here with those obtained in other muscles. In amphibian skeletal muscle the delay between onset of the light signal and onset of tension is 5–10 ms at 10 °C (ref. 1); in mammalian Purkinje fibres it is 18–20 ms at 35 °C (ref. 2); in amphibian smooth muscle the delay is greater than 200 ms at 25 °C (ref. 7), whereas for the slow response in our mammalian smooth muscle preparation at 35 °C the delay is 100–160 ms. The value of this latency was not reported for molluscan smooth muscle<sup>6</sup>. Thus, in this respect, mammalian smooth muscle seems to resemble amphibian smooth muscle more closely than the other muscle types. However, the time to peak amplitude of the light responses in mammalian smooth muscle is much greater than in amphibian muscle. Amphibian smooth muscle has a time to peak of only 3 or 4 ms and the light transient is virtually over well before tension development. In contrast, this mammalian smooth muscle has a time to peak of 200–800 ms and a peak light emission coincident with the development of tension. The time to peak for molluscan smooth muscle is similarly long, reaching 1 s or more and corresponding with the development of tension. For comparison, skeletal and cardiac muscles have times to peak of 4 and 8–20 ms, respectively, and the peak light emission occurs during the phase of tension development.

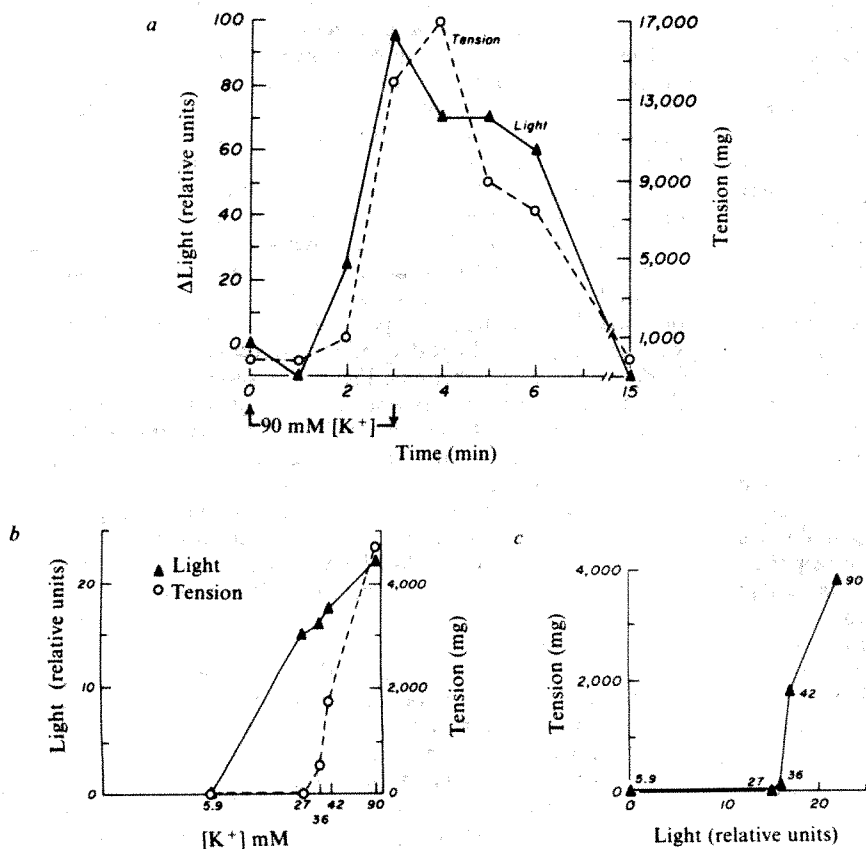

The observation that light emission and hence  $[\text{Ca}_i^{2+}]$  of mammalian smooth muscle rises for a period of more than 100 ms before there is any detectable increase in tension may be interpreted in several ways; either there are relatively slow steps between the elevation of  $\text{Ca}_i^{2+}$  and tension development, or  $[\text{Ca}_i^{2+}]$  is below a threshold concentration necessary for the development of force and some time would be taken in reaching this level, or both of these alternatives occur. The second possibility is supported by the report that this tissue has a voltage threshold for contraction some 30 mV positive to its resting potential<sup>11,12</sup>. To test this possibility and also to determine whether  $[\text{Ca}_i^{2+}]$  is voltage dependent, we recorded calcium levels in depolarized preparations. Figure 2a shows the changes in light and tension with time when an antral strip was depolarized with a solution containing 90 mM  $\text{K}^+$ . This preparation had a 'resting glow' detectable signal averaging. In 5 of 13 preparations demonstrating such a resting glow, there was a decrease in light intensity during the first minute of exposure, however, no regular pattern in this occurrence was noticed. Concentrations of  $\text{K}^+$  of 18–27 mM depolarized the membrane by approximately 15–30 mV (refs 11, 12) and caused increases in light but no increase in tension. Higher levels of  $\text{K}^+$  caused concentration-related increases in light and tension. Figure 2b shows typical plots of both light and tension as a function of  $[\text{K}^+]$  while in Fig. 2c these data are presented as a function of light against tension. Clearly light increased as the  $[\text{K}^+]$  was raised to 27 mM but there was negligible increase of tension up to this level. Microscopic examination of the tissue in these low  $[\text{K}^+]$  solutions failed to reveal any evidence of internal shortening. Thus,  $[\text{Ca}_i^{2+}]$  was increasing at values of membrane potential

\* Present address: Department of Physiology and Pharmacology, University of New South Wales, Box 1, PO Kensington, Sydney, Australia

**Fig. 1** *a*, Simultaneous recordings of light (upper trace) and force of isometric contraction. Light is measured in counts per s from a photon-counting system and force is measured in grammes from a Satham force transducer with a natural frequency of 250 Hz. Individual light and tension responses elicited by 10-ms, 50-V stimuli are shown. The preparation was stimulated through a pair of Pt wires 15 mm apart and parallel to the axis of the circular fibres. Stimulus voltage was chosen to be supramaximal for contraction. Electrical stimuli of these parameters triggered action potentials in this tissue. About 40 cells in this preparation were injected with aequorin. The injection of aequorin had no detectable effect on membrane potential or action potential generation in this spontaneously active tissue. *b*, 32 simultaneous light and tension signals have been averaged to obtain this record. The light signal has been filtered with a 50-ms time constant. *c*, Expanded time scale of the data shown in *b*; recorded with a 1-ms time constant. Arrowhead denotes the brief response associated with stimulus.

**Fig. 2** *a*, Effect of 90 mM K<sup>+</sup> on light emission and isometric tension development. The high [K<sup>+</sup>] solution was substituted for normal Krebs solution at 0 time. ○, Tension; △, light; each data point represents the average of 60, 1-s segments of both light and tension recordings before, during and after exposure to K<sup>+</sup>. High [K<sup>+</sup>] was washed out in this experiment before steady state was established. *b*, Relationship between [K<sup>+</sup>] and light and tension. All data points are from the same preparation, and taken for steady-state responses to each solution. 5.9 mM is the concentration of K<sup>+</sup> in the normal Krebs. *c*, Relationship between light and tension induced by different levels of [K<sup>+</sup>]. This graph shows the same data as *b*. The number beside each symbol represents the [K<sup>+</sup>]. Solutions of high [K<sup>+</sup>] were prepared by equimolar substitution of K<sup>+</sup> for Na<sup>+</sup>. Temperature in all experiments was 32–35 °C (constant in any one experiment).

subthreshold for contraction. This observation supports the contention that resting calcium levels in this tissue are somewhat below a calcium threshold. As this tissue does not normally demonstrate active tone, it may be that such tissues are distinguished from tissues with tonic activity by the level of resting intracellular free calcium concentration.

Whether this 'calcium threshold' is the threshold level of  $\text{Ca}^{2+}$  which activates the myofilaments or that which causes sufficient activation to take up the compliance of the tissue was not determined. Note, however, that with smooth muscle from the fundal region of the stomach<sup>11</sup>, and using the same apparatus for recording contractile tension, significant tension development is detected with as low a  $[\text{K}^+]$  as 12 mM.

Recently, it has been suggested that the action of  $\text{Ca}^{2+}$  on the contractile system of smooth muscle is not direct but, rather, that the  $\text{Ca}^{2+}$  activates a protein kinase which phosphorylates the

myosin and stimulates myosin's interaction with actin<sup>13-15</sup>. This possibility has been used to explain the long delay between the calcium transient and contraction in amphibian smooth muscle<sup>7</sup>. As we do not observe any similar delay in our mammalian smooth muscle preparation, we conclude that such phosphorylation either is not required in mammalian smooth muscle at 35 °C or that it is considerably more rapid than in amphibian smooth muscle at 24 °C. We favour the latter interpretation because the long time course of dephosphorylation<sup>16</sup> could explain the lag between the return of  $[\text{Ca}^{2+}]$  to basal levels and the relaxation of the muscle.

We thank J. R. Blinks and J. H. Szurszewski for many valuable contributions. We also acknowledge use of the facilities of the Friday Harbor Laboratories, University of Washington, for the collection of aequorin. Financial support was provided by the Minnesota Heart Association and USPHS grants AM 17238, HL 12186, HL 07111.

## External Na dependence of ouabain-sensitive ATP:ADP exchange initiated by photolysis of intracellular caged-ATP in human red cell ghosts

Jack H. Kaplan & Richard J. Hollis

Department of Physiology and Biophysics, University of Iowa, Iowa City, Iowa 52242

Coupled active transport of  $\text{Na}^+$  and  $\text{K}^+$  across cellular plasma membranes is mediated by  $(\text{Na}^+ + \text{K}^+)$ -stimulated  $\text{Mg}^{2+}$ -dependent ATPase. Active cation transport by this Na pump involves a cyclic Na-dependent phosphorylation of the enzyme by intracellular ATP and hydrolytic dephosphorylation of the phosphoenzyme, stimulated by  $\text{K}^+$  (ref. 1). In human red blood cells<sup>2</sup>, skeletal muscle<sup>23</sup> and squid axons<sup>3,4</sup>, replacement of extracellular K by Na results in a ouabain-sensitive efflux of Na coupled to an influx of extracellular Na. There is apparently no net Na movement<sup>5</sup> nor net hydrolysis of ATP<sup>6</sup>. The rate of Na:Na exchange is stimulated by increased levels of ADP<sup>7</sup> and exchange transport is not observed in cells totally depleted of intracellular ATP<sup>8</sup>. These characteristics suggest that the biochemical mechanism underlying the Na exchange mode of the Na pump involves phosphorylation of the enzyme by ATP (which requires intracellular Na) followed by its dephosphorylation by ADP. Such a reaction has been observed in partially purified  $(\text{Na}^+ + \text{K}^+)$ ATPase from a variety of sources<sup>9-11</sup> and its dependence on Na concentration has been described<sup>12,13</sup> (although not previously for the red cell enzyme). In the present work, intracellular ATP:ADP exchange reaction was initiated by photoreleased ATP following brief irradiation at 350 nm of ghosts containing caged-ATP<sup>14</sup>. The ouabain-sensitive component of the ensuing ATP:ADP exchange reaction shows a biphasic response to extracellular Na. External Na in the range 0-10 mM has an inhibitory effect whilst increasing concentrations beyond this range stimulate the rate of exchange in a roughly linear fashion up to 100 mM Na. These results represent the first direct demonstration of the sidedness of the effects of Na on this partial sequence in the overall enzyme cycle and bear a qualitative resemblance to the Na effects on the Na-ATPase which occur in the absence of intracellular ADP in human red blood cells<sup>15</sup>.

The biochemical reaction of interest in the present context may be represented as,

and can be measured as the ouabain-sensitive rate of production of  $^3\text{H}$ -ATP from  $^3\text{H}$ -ADP. Although the availability of resealed erythrocyte ghosts has made possible the independent manipulation of intracellular and extracellular cation concentrations, in order to measure the ATP:ADP exchange reaction, three major experimental difficulties had to be overcome: (1) high cytoplasmic adenylate kinase activities (approximately 5 mol per litre of cells per hour); (2) high cytoplasmic nucleoside diphosphokinase (NPDK) activities; (3) endogenous ATPase activities. Furthermore, the preparation of resealed ghosts requires a lengthy incubation procedure for resealing. Since the reaction of interest involves isotopic exchange in the intracellular compartment a recycling system is not appropriate and to measure initial rates of the unidirectional reaction it is necessary that the reaction be initiated after ghost preparation is completed.

Following the lead of Cavieres and Glynn<sup>8</sup> we prepared resealed ghosts with a large dilution of cellular contents and incorporated inside the ghosts the competitive inhibitor of adenylate kinase, diadenosine pentaphosphate ( $\text{Ap}_5\text{A}$ ) (ref. 16). Using a gel filtration column for cell lysis and cytoplasmic dilution<sup>17</sup> and incorporating 50  $\mu\text{M}$   $\text{Ap}_5\text{A}$  into the ghosts we have been able to prepare ghosts containing up to 250  $\mu\text{M}$   $^3\text{H}$ -ADP which after incubation at 37 °C for 2 h contained  $^3\text{H}$ -AMP at levels that were no higher than originally present in the  $^3\text{H}$ -ADP as a contaminant (about 4%). The presence of high cytoplasmic NPDK activities in human erythrocytes is well documented<sup>18</sup> (approximately 5 mol per litre cells per h) and we find that sufficient activity is present even in 300-fold diluted hemolysates to generate micromolar levels of ATP from micromolar ADP and millimolar UTP within several minutes. The enzyme performs the same reaction as the one of interest mediated by the Na pump, that is, the production of  $^3\text{H}$ -ATP from  $^3\text{H}$ -ADP via the dephosphorylation of a phosphoenzyme intermediate. The brain NPDK enzyme is inhibited by Cibacron blue F3GA (J. B. Robinson and E. C. Stellwagen, personal

communication). Unfortunately, although this dye is also a very potent inhibitor of the cytoplasmic red cell enzyme, it partitions predominantly into cell membranes. The inhibition of cytoplasmic NADK activity in red cell haemolysates containing Cibacron blue is removed on the addition of red cell membranes (J.H.K. and R.J.H., unpublished data). Amongst the class of dyes which inhibit nucleotide-requiring enzymes<sup>19</sup>, Trypan blue (CI 23850) was found to inhibit cytoplasmic NADK activities in the absence and presence of red cell membranes and in resealed red cell ghosts, without affecting  $(\text{Na}^+ + \text{K}^+)\text{ATPase}$  activities.

To avoid the problems associated with endogenous ATPase activity during ghost incubations at 37 °C (which are required to reseal the ghosts) and also in order to initiate the exchange reaction, we have incorporated caged-ATP into the ghosts. Caged-ATP,  $\text{P}^3\text{-1-(2-nitro)phenylethyl-ATP}$ , is an ATP analogue in which the terminal phosphate of ATP is esterified by a 2-nitrobenzyl moiety. Caged-ATP is resistant to ATPase

activity because of the esterification of the terminal phosphate residue and is unable to perform ATP-dependent reactions which require phosphorylation. The 2-nitrobenzyl residue is cleaved from the rest of the molecule by irradiation at 350 nm, releasing ATP<sup>14</sup>. We have used caged-ATP as a stable source of ATP that will not undergo reaction during ghost preparation but which subsequently can be 'activated' by the photorelease procedure.

Figure 1 illustrates the Na dependence of ATP:ADP exchange rates in porous red cell membranes. The curve is very similar to that seen using partially purified enzyme from pig kidney outer medulla<sup>10</sup> or dog kidney outer medulla (J.H.K. and M. D. Mone, unpublished), although the specific activity in red cell membranes is some 2–3 orders of magnitude lower than the kidney preparations.

In order to decide which of the Na effects are mediated at extracellular sites, resealed red cell ghosts were prepared containing,  $\text{MgSO}_4$ , NaCl, choline Cl, the kinase inhibitors,

**Fig. 1** The Na dependence of ATP:ADP exchange in porous red cell membranes. Haemoglobin-free membranes were prepared essentially according to the method of Fairbanks *et al.*<sup>21</sup> by lysis of cells at 0 °C in 20 vol of 5 mM sodium phosphate pH 8. Before lysis the cells were washed in 150 mM  $\text{NaHCO}_3$  pH 8.2 to facilitate haemoglobin release<sup>22</sup>. Until use, the white membranes were stored at -20 °C. Thawed membranes were suspended in 5 mM EDTA, 10 mM HEPES pH 7.5 (at 0 °C), incubated at room temperature for 10 min and pelleted (35,000 g, 15 min). The pellet was then resuspended in 150 mM choline chloride, 10 mM HEPES pH 7.6 in 50  $\mu\text{l}$  aliquots at a protein concentration of approximately 3 mg  $\text{ml}^{-1}$ . The reactions were then carried out at 23 °C following the addition of an equal volume of buffered solution containing (final concentration) NaCl + choline chloride to 150 mM, 10 mM  $\text{MgCl}_2$ , 25  $\mu\text{M}$   $^3\text{H}$ -ADP, 25  $\mu\text{M}$  ATP, 100  $\mu\text{M}$   $\text{Ap}_3\text{A}$  and 10 mM HEPES pH 7.6. The reaction was started by the addition of the nucleotides and sampled by quenching in ice-cold 10% trichloroacetic acid at 0.25, 5.25 and 10.25 min. The samples were then frozen before processing. The thawed samples were centrifuged for 2 min at 10,000 g in a Eppendorf microfuge, to pellet the denatured membranes, and samples of the supernatant applied to polyethyleneimine thin layer chromatography plates. The plates were dried and samples of a solution containing 4 mM each of ATP, ADP and AMP applied on top of the experimental samples. The plates were then developed in 0.4 M K phosphate, pH 3.5 and the regions containing ATP, ADP and AMP, visualized using an UV lamp, cut out and placed in scintillation vials. Following the addition of HCl (1 M, 0.5 ml) the vials were placed in an oven at 120 °C for 30 min. After cooling, scintillation fluid was added and then radioactivity co-migrating with each nucleotide counted. Recovery of radioactivity using this procedure was always between 97% and 103% of the amount applied to the chromatography plate. The rates were linear over the time period of the reaction and the initial rate calculated. The curves shown depict the dependence of the exchange rate on Na concentration in experiments using three different preparations of membranes. The open symbols are rates obtained in the absence of Na with  $10^{-4}$  M ouabain in the medium. In the lowest curve Na concentrations between 0 and 5 mM were not used. Although the dependence of rate upon Na concentration was the same in different membrane preparations, the absolute rates did show some variation in different preparations.

**Fig. 2** Photolytic initiation of the ATP:ADP exchange reaction in resealed red cell ghosts. Freshly drawn blood was collected in heparinized tubes and the red cells washed three times in 150 mM choline chloride, 10 mM HEPES pH 7.6 by centrifugation (14,000 g, 5 min), removal of supernatant and resuspension. After the second resuspension the cells were incubated at room temperature for 10 min to ensure completion of pH equilibration. A 10% (by vol) suspension of the cells in the choline buffer was cooled to 0 °C. The suspension was then introduced into the top of a jacketed column of Biorad A50m gel (35 cm  $\times$  5.0 cm) maintained at -1 °C. The column had previously been prepared so that the lower half was equilibrated with 15 mM PIPES, 0.1 mM EDTA pH 6.0, the middle four-tenths of column volume with 20 mM HEPES, pH 7.5 and the upper one-tenth with 150 mM choline Cl, 10 mM HEPES pH 7.6. After introducing the cells into the column they were eluted with buffered choline Cl. The eluate was collected in ice-cold tubes as soon as turbidity was observed in the eluate leaving the column. At this stage the red band of haemoglobin was approximately half-way down the column. The fractions containing membranes were bulked and collected by centrifugation at 0 °C, 31,000 g for 15 min. The supernatant was removed and ice-cold reversal solution containing choline Cl + NaCl (150 mM), 50  $\mu\text{M}$  Trypan blue, 100  $\mu\text{M}$   $\text{Ap}_3\text{A}$ , 10  $\mu\text{M}$   $\text{MgSO}_4$ , 50  $\mu\text{M}$  caged-ATP, 25  $\mu\text{M}$   $^3\text{H}$ -ADP, 10 mM HEPES pH 7.6 was added to the pale pink pellet. After resuspension and incubation in ice for 5 min, the membranes were transferred to a water bath at 37 °C for a further 45 min. The resealed ghosts were then washed three times in 150 mM choline Cl, 10 mM HEPES pH 7.6 by centrifugation (31,000 g, 5 min) and resuspension. The ghosts were packed after the final wash (31,000 g, 15 min) and resuspended in 10% suspension (by vol) in 100 mM NaCl, 50 mM choline Cl, 10 mM HEPES pH 7.6. Aliquots (200  $\mu\text{l}$ ) of the suspension were photolysed in 1 mm path length cuvettes as previously described<sup>14</sup> and at suitable time intervals samples (20  $\mu\text{l}$ ) were added to ice-cold 10% trichloroacetic acid (20  $\mu\text{l}$ ) and rapidly mixed. Duplicate samples were added to distilled water (200  $\mu\text{l}$ ) and placed in a boiling water bath for 1 min. The boiled samples were then cooled and assayed for ATP, ADP and AMP contents using a modification of the procedure of Kimmich *et al.*<sup>20</sup> The samples in trichloroacetic acid were treated as described in the legend to Fig. 1. The filled symbols indicate the rate of appearance of radioactivity in intracellular ATP, the open symbols the rate in the presence of  $10^{-4}$  M ouabain in the external medium. During the time of reaction ATP hydrolysis was less than 5%. The reaction was initiated by photolysis at zero time, the vertical arrow indicates when photolysis was stopped. In unphotolysed ghosts less than 0.04% of the total radioactivity migrated with ATP.

$^3\text{H}$ -ADP and caged-ATP and photolysed to initiate the exchange reaction. A representative time course of the appearance of  $^3\text{H}$ -ATP in such an experiment is shown in Fig. 2. It is clear that a major component of the total exchange reaction is ouabain-sensitive, that is, mediated by the Na pump. Figure 3 shows the data from experiments in which external Na has been systematically varied. In each experiment the rate of ATP:ADP exchange was measured in aliquots of the ghosts suspended at various external Na concentrations. The curves depict the variation of the ATP:ADP exchange rate as a function of the external Na concentration at constant internal Na.

Thus Na pump-mediated ATP:ADP exchange in resealed human red cell ghosts shows a biphasic dependence on extracellular Na concentration. These observations enable us to identify unambiguously each of the three limbs of the Na activation curve in Fig. 1 with intracellular or extracellular sites for Na. At least three classes of sites are observed on the porous membranes (Fig. 1) and of these, the two of lower affinity can now be localized to the extracellular surface of the cell membrane. The higher-affinity extracellular site inhibits the ATP:ADP exchange reaction in the range 0–10 mM Na, the lower affinity site stimulates the reaction in an approximately linear fashion up to 100 mM Na, and thus saturates well beyond the physiological range. The highest affinity Na sites are intracellular and presumably support enzyme phosphorylation. It has been suggested that the stimulation of ATP:ADP exchange reaction rate seen at high Na levels with porous enzyme preparations is due to an increase in the steady-state level of ADP-sensitive phosphoenzyme<sup>13</sup>. Our data extend the earlier observations to include red cell membranes and further specify that the Na sites which are involved in this stimulation are sites for external Na.

The effects of external Na on ATP:ADP exchange described here parallel the dependence of Na:Na exchange in red blood cells on external Na concentration<sup>5</sup>. The question of the relative rates of these reactions has not been directly addressed in the present studies. It would be interesting to know how many Na ions are transported across the membrane each time the phosphorylated pump protein is dephosphorylated by ADP. Although Na entry may require the dephosphorylation step<sup>7</sup> the converse is apparently not true. When external Na is zero and Na entry cannot take place ATP:ADP exchange does occur (Fig. 3). Under these conditions it is not known whether a Na efflux occurs, whether internally bound Na is discharged into the cytosol or whether internal Na remains bound to the enzyme.

Fig. 3 Dependence of the rate of ATP:ADP exchange on extracellular Na. The procedures used to prepare the ghosts and determine the rate of ATP:ADP exchange were as described in the legends to Figs 1 and 2. The ghosts were suspended in media containing varying Na concentrations before photolysis, maintaining the sum NaCl + choline Cl at 150 mM. The three curves illustrate data from three different batches of resealed ghosts. The open symbols show the rate of ATP:ADP exchange in the absence of extracellular Na and in the presence of  $10^{-4}$  M ouabain. Intracellular Na was determined by flame photometry and was between 11 mM and 16 mM in these experiments.

The determination of the relationship between the rates of isotopic Na movements and ATP:ADP exchange awaits their measurement under varied identical conditions in the same preparation.

We thank Linda J. Kenney for technical assistance, Dr P. G. Wood for advice on gel filtration in the preparation of Haemoglobin-free ghosts and Dr K. G. Beam for comments on the manuscript. This work was supported by NIH grant HL24309 to J.H.K. and by a starter grant from the PMA Foundation.

## Potent carcinogenicity of nitrosodiethanolamine in rats

W. Lijinsky, M. D. Reuber & W. B. Manning

Chemical Carcinogenesis Program, NCI Frederick Cancer Research Center, Frederick, Maryland 21701

Nitrosodiethanolamine is found in synthetic cutting oils and in many cosmetic preparations and is probably the *N*-nitroso compound to which human exposure is greatest<sup>1–3</sup>. It is formed by reaction of the commonly used amines diethanolamine and triethanolamine<sup>4</sup> with nitrosating agents. An assessment of the possible risk in human exposure to nitrosodiethanolamine must be based on sound chronic toxicity data. A previously published chronic test of this compound in rats has shown it to induce liver tumours after very high oral doses<sup>5</sup>, and tumours of the nasal cavity after administration of high repeated doses to Syrian hamsters by subcutaneous injection<sup>6</sup>. To improve our understanding of the carcinogenic potency of nitrosodiethanolamine, we undertook a more extensive study, in which the compound was administered at concentrations ranging from 3,900 to 31,250 parts per million (p.p.m.) in drinking water, to groups of rats for about 6 months. We report here that when the animals were killed, all bore hepatocellular carcinomas, many of which metastasized at the higher doses, indicating that nitrosodiethanolamine is a carcinogen of considerable potency in the rat. However, it is inactive or very weakly active in short-term tests, such as the *Salmonella* mutagenesis test developed by Ames<sup>7</sup>.

Sixty male and sixty female Fischer 344 rats of the colony of the Frederick Cancer Research Center, bred and raised in SPF conditions, were housed in plastic cages with wire-mesh bottoms (five rats per cage). The animals were 6–7 weeks old at the beginning of the experiment, and were randomized into (for

*N*-nitrosodiethanolamine was prepared on a large scale as follows. To a 6,000-ml Erlenmeyer flask cooled in an ice bath were added 1 kg diethanolamine (Aldrich), 1.24 kg sodium nitrite (Mallinckrodt) and 1.3 l water. After preliminary agitation to disperse the undissolved solid, the mixture was stirred magnetically overnight. To the homogeneous solution cooled to 0–5 °C in an ice bath was added 1.7 l 12 M HCl dropwise over a period of 4–5 h. Large volumes of brown nitrogen dioxide were evolved. On completion of the acid addition, stirring was continued for 1 h, after which 1,000 ml of methanol was slowly added to the still cold solution. Evolution of methyl nitrite ensued and dictated the rate of methanol addition. The flask was left overnight to complete transesterification. Salts present were removed by filtration using a fritted glass funnel. The filtrate was treated with small portions of a saturated sodium carbonate solution until a pH of 8 was attained. The colour of the solution changed from pale green to golden yellow. This solution was reduced to a viscous suspension by removing a large amount of water on a rotary evaporator. Anhydrous acetone was added to the suspension to decrease the viscosity and the salts in the suspension were removed by vacuum filtration. The filtrate was again reduced to a viscous suspension by removing acetone and residual water. To this suspension was added an equivalent volume of anhydrous acetone and the resulting mixture was filtered to remove the precipitated salts. Acetone was removed from the filtrate to give a golden yellow liquid of high viscosity. Analysis of this material by NMR spectrometry, IR spectrometry and UV spectrometry gave results consistent with the structure of nitrosodiethanolamine and indicated high purity. When 100 g was extracted four times with 100 ml of methylene chloride, the extract concentrated and the residue analysed by gas-liquid chromatography, no identifiable volatile nitrosamines were found at a detection level of 0.03 p.p.m.

each sex) 6 groups of 10. One of the groups served as untreated controls and the remainder were given solutions of nitrosodiethanolamine in neutral (pH 7) tap water that had been filtered through a deionizer. The concentrations of nitrosodiethanolamine and the numbers of animals treated are shown in Table 1.

Treatment consisted of giving the nitrosodiethanolamine solutions at 20 ml per rat each day on 5 days of each week; on the remaining 2 days the animals were given tap water without the nitrosamine. In these conditions almost all the nitrosamine solution was consumed, with little spillage (the tap water was given to replenish any water deficit suffered by the animals). Due to an error in communication, for the first 12 weeks of the experiment the nitrosamine solutions were supplied *ad libitum* for 7 days of each week; this hampered calculation of the exact doses received by each cage of animals, as the animals given the higher concentrations tended to drink more of the drug-containing solution (perhaps it has an appetizing taste). An exception was the 62,500 p.p.m. solution, of which little was drunk and which proved quite toxic, leading to the death of several animals within 2 weeks; treatment with this concentration of nitrosodiethanolamine was discontinued and the animals were discarded.

After 12 weeks the designated treatment regimen was restored and treatment was continued until 34 weeks after the beginning of the experiment. A few animals at the 31,250 and 15,600 p.p.m. concentrations died before the 34th week. All surviving animals were killed at week 34. The dead animals were completely necropsied and all lesions, with most normal tissues, were fixed for histological evaluation.

All the animals in the four long-term treated groups developed hepatocellular carcinomas of the liver. At the higher doses most rats also had cholangiocellular carcinomas. Histologically the hepatocellular carcinomas varied from well differentiated to poorly differentiated to undifferentiated, whereas the cholangiocarcinomas were well differentiated; each liver contained multiple large, invasive carcinomas. None of the untreated control animals had lesions of the liver. At the 31,250 and 15,600 p.p.m. doses, many of the liver carcinomas metastasized to the lungs and peritoneal cavity (Table 1).

Nitrosodiethanolamine is therefore a more potent carcinogen for the liver of Fischer 344 rats than was previously suspected. As liver carcinomas were induced after administration of a

solution containing 3,900 p.p.m. for only 34 weeks, it is likely that considerably lower concentrations will be effective. During most of the experiment the dose of nitrosodiethanolamine received by the animals was kept at 100 ml of solution per week, corresponding to 390 mg of nitrosodiethanolamine per week. This amounted to ~13 g per rat over the course of the treatment or 30 g per kg body weight for the males and 50 g per body weight for the females. This contrasts with the experiment of Druckrey *et al.*<sup>5</sup>, in which a total dose of 150–300 g of nitrosodiethanolamine per kg body weight gave rise to liver tumours in BD rats with a median induction time of 42 weeks.

Concentrations of nitrosodiethanolamine in some cutting oils reaches 3% or 30,000 p.p.m. (ref. 1) and in some cosmetics 48 p.p.m. (ref. 3). Therefore, the data presented here imply that the doses of this compound to which much of the human population is exposed can no longer be dismissed on the grounds that it is a weak carcinogen. Notably nitrosodiethanolamine has been found to penetrate rat skin quite readily<sup>6</sup>, so that skin contact with materials containing nitrosodiethanolamine is likely to present a carcinogenic risk to humans.

A similar study to that in rats was conducted with B6C3F<sub>1</sub> mice, groups of 10 female and 10 male mice being given nitrosodiethanolamine solutions in concentrations of 62,500–3,900 p.p.m. in water. In this case each mouse was allotted 5 ml of solution per day, 5 days a week for 32 weeks. Unlike the rats, mice tolerated the 62,500 p.p.m. concentration quite well. At the end of the study cholangiofibrosis and cirrhosis, as well as some hyperplastic nodules, were found in the livers of many mice receiving the higher doses of nitrosodiethanolamine, but no tumours were observed. This suggests that B6C3F<sub>1</sub> mice are less susceptible to the carcinogenic action of nitrosodiethanolamine than are F 344 rats.

Radiological Research Laboratory, Department of Radiology and Department of Pathology, College of Physicians and Surgeons, Columbia University, New York, New York 10032

**The direct oncogenic potential of X rays has been demonstrated by the *in vitro* neoplastic transformation of mammalian cells in culture<sup>1</sup>, a technique which permits the study of oncogenesis in the absence of host-specific effects. Although several agents are known to modulate *in vitro* neoplastic transformation by X rays<sup>2</sup>, little is known of the effects of hormones. We now describe experiments which show that the presence of thyroid hormone is necessary for *in vitro* neoplastic transformation by X rays in cells of an established mouse fibroblast culture (C3H/10T1/2) and in early-passage diploid hamster embryo cells.**

Animal studies have shown that altered thyroid status modifies the growth and metastatic potential of implanted tumours<sup>3</sup> as well as the survival rate of animals bearing tumours<sup>6</sup>. We therefore set out to investigate whether this modulation is a direct effect of the hormone on neoplastic transformation. *In vitro* transformation by X rays has been especially well investigated in early-passage primary hamster embryo cells in culture<sup>7,8</sup> and C3H/10T1/2 mouse embryo fibroblasts<sup>9-11</sup>, and qualitatively demonstrated in human diploid cells<sup>12</sup>. Accordingly we have used in this study (1) short-term cultures of diploid hamster embryo cells (HE) obtained as previously described<sup>1,2,7,8</sup>, and (2) the C3H/10T1/2 clone 8 mouse embryo heterodiploid cell line developed by Reznikoff *et al.*<sup>13</sup>.

We have measured the efficacy of X rays in inducing neoplastic transformations in cell cultures of both types when thyroid hormone has been removed from the culture medium and find

that transformation is inhibited. We have also shown that the efficacy of X rays in causing neoplastic transformation is restored when thyroid hormone (triiodothyronine, T<sub>3</sub>) is added to the hormone-depleted medium.

Both cell types are fibroblast-like cells. Cell transformation was detected morphologically and scored as described elsewhere for the hamster embryo cells<sup>1,2,7,8</sup> and for the C3H/10T1/2 mouse cells<sup>9-11,14</sup>. In these earlier studies, the morphological changes associated with the transformed state have been correlated with the oncogenic potential of the cells. The procedures used are described in detail in Table 1 legend. Thyroid hormones (T<sub>3</sub> and thyroxine, T<sub>4</sub>) were removed from heat-inactivated fetal bovine serum as described by Samuels *et al.*<sup>15</sup> using AG1-X10 resin (Biorad). In each experiment, six different experimental culture conditions were used: (1) resin-treated serum (-T<sub>3</sub>), unirradiated; (2) resin-treated serum (-T<sub>3</sub>), irradiated; (3) resin-treated serum, T<sub>3</sub> (Sigma) added (+T<sub>3</sub>), unirradiated; (4) resin-treated serum, T<sub>3</sub> added (+T<sub>3</sub>), irradiated; (5) untreated serum, unirradiated; and (6) untreated serum, irradiated. Table 1 shows that when cells are maintained in media depleted of thyroid hormones (-T<sub>3</sub>), X-ray irradiation-induced transformation is dramatically inhibited in both cell types tested. To support further the role of thyroid hormone in transformation, only T<sub>3</sub> was re-added to resin-treated, serum-supplemented media; the observed transformation frequency on re-addition was similar to control, irradiated cells maintained in untreated-serum-supplemented media.

A dose-response curve for cell survival was carried out, as described elsewhere<sup>7,8</sup>, on each cell type to determine if the elimination of thyroid hormone would differentially affect the survival of the cells after X-ray irradiation. We found that the removal of thyroid hormones from the serum, or the resin treatment, had very little effect on the survival of either cell type (data not shown). Further, it was determined in both cell types that the growth characteristics of cells grown in the absence of T<sub>3</sub> were identical to the growth in the presence of T<sub>3</sub> in resin-treated, serum-supplemented media.

These data indicate that X-ray irradiation-induced *in vitro* transformation of mammalian cells is dramatically inhibited when cells are maintained in the absence of thyroid hormone. This seems to be a direct effect of the hormone as the expected frequency of transformation is restored when T<sub>3</sub> is reintroduced in the culture medium. These results cannot be ascribed to differences in survival or growth characteristics of the cells maintained in the presence or absence of thyroid hormone.

**Table 1** The effect of thyroid hormone on X ray irradiation-induced cell transformation *in vitro* of C3H/10T1/2 mouse cells and hamster embryo cells in culture

| Cells      | Serum treatment/(T <sub>3</sub> condition)             | X rays (Gy) | Total surviving colonies | No. of colonies transformed | Transformation frequency |
|------------|--|-------------|--------------------------|-----------------------------|--------------------------|
| C3H/10T1/2 | Untreated FBS  | 0           | 23,313                   | 0                           | 0                        |
|            | Untreated FBS  | 3           | 27,737                   | 24                          | 8.65 × 10 <sup>-4</sup>  |
|            | Resin-treated FBS/(-T <sub>3</sub> -T <sub>4</sub> )   | 0           | 23,154                   | 0                           | 0                        |
|            | Resin-treated FBS/(-T <sub>3</sub> -T <sub>4</sub> )   | 3           | 33,747                   | 0                           | 0                        |
|            | Resin-treated FBS + T <sub>3</sub> /(+T <sub>3</sub> ) | 0           | 15,884                   | 0                           | 0                        |
|            | Resin-treated FBS + T <sub>3</sub> /(+T <sub>3</sub> ) | 3           | 21,040                   | 16                          | 7.60 × 10 <sup>-4</sup>  |
| HE         | Untreated FBS  | 0           | 2,800                    | 0                           | 0                        |
|            | Untreated FBS  | 2.2         | 4,800                    | 16                          | 3.33 × 10 <sup>-3</sup>  |
|            | Resin-treated FBS/(-T <sub>3</sub> -T <sub>4</sub> )   | 0           | 2,400                    | 0                           | 0                        |
|            | Resin-treated FBS/(-T <sub>3</sub> -T <sub>4</sub> )   | 2.2         | 1,500                    | 0                           | 0                        |
|            | Resin-treated FBS + T <sub>3</sub> /(+T <sub>3</sub> ) | 0           | 2,600                    | 0                           | 0                        |
|            | Resin-treated FBS + T <sub>3</sub> /(+T <sub>3</sub> ) | 2.2         | 3,600                    | 15                          | 4.17 × 10 <sup>-3</sup>  |

Values given are totals of three separate experiments with C3H/10T1/2 cells and two separate experiments with hamster embryo cells. Stock 10<sup>-3</sup> M T<sub>3</sub> in 50% *n*-propanol was diluted in media with 10% resin-treated fetal bovine serum (FBS) to give a final concentration of 10<sup>-7</sup> M T<sub>3</sub> (designated +T<sub>3</sub>). Media without thyroid hormone was prepared with 10% resin-treated FBS and an amount of diluent equal to that added in the +T<sub>3</sub> media. Stock cultures of C3H/10T1/2 cells were maintained in Eagle's basal medium +10% heat-inactivated FBS; hamster embryo cells in Dulbecco's modified Eagle's medium +10% FBS. Both cultures contained penicillin (50 U ml<sup>-1</sup>) and streptomycin (50 µg ml<sup>-1</sup>). All cells were maintained at 37 °C with 5% CO<sub>2</sub> in air throughout the experiment. One week before seeding, stock cultures were placed in the experimental culture media, with and without T<sub>3</sub> (as described in the text) and maintained in these conditions for the duration of the experiment. Twenty-four hours after seeding, the cells were irradiated with X rays at room temperature (2.2 Gy for HE and 3 Gy for C3H/10T1/2 cells), at a dose rate of 0.322 Gy min<sup>-1</sup>, thereafter receiving weekly media changes. After an appropriate incubation period (6 weeks for C3H/10T1/2 and 2 weeks for HE), the cells were fixed and stained with Giemsa and scored for transformation. Both type II and III foci were scored in C3H/10T1/2 experiments.

Experiments, to be published in more detail elsewhere, indicate that when cells are exposed to concentrations of  $T_3$  ranging from  $10^{-11}$  M to  $10^{-7}$  M, X-ray-induced transformation is dose dependent. Additionally, these studies demonstrate that the critical period of exposure to the hormone is a 12-h period before irradiation. This suggests that, in these experimental conditions, thyroid hormone is necessary for the induction and/or potentiation of X-ray irradiation-induced transformation *in vitro*. Thyroid hormone may also have a significant, perhaps even decisive, role in the occurrence of neoplastic transformation *in vivo*. Studies are in progress to define possible mechanisms of action and the involvement of thyroid hormone in neoplastic transformation *in vitro* by chemicals and viruses.

D.L.G. was the recipient of National Research Service Award AM-05948 from the NIH. This investigation was supported by NIH grants CA-22376 and AM-07328, by grant CA-12536 to the Radiological Research Laboratory/Department of Radiology, and grant CA-13696 to the Cancer Center/Institute of Cancer Research awarded by the NCI, DHEW and by contract DE-AC02-78EV04773 from the Department of Energy. We thank Dr I. S. Edelman for providing facilities and support for part of this research. Dr C. Heidelberger provided the C3H/10T1/2 clone 8 mouse embryo heterodiploid cell line.

## Friend leukaemia virus-transformed cells, unlike normal stem cells, form spleen colonies in *Sl/Sl<sup>d</sup>* mice

Dixie Mager, Tak W. Mak & Alan Bernstein

The Ontario Cancer Institute and Department of Medical Biophysics, University of Toronto, Toronto, Ontario, Canada M4X 1K9

Neoplastic cells are characterized by partial or total autonomy from the interactions that regulate the behaviour of normal cells in the intact animal. Despite the role of the host cellular environment in governing the proliferation and differentiation of both normal and malignant cells, little is actually known about these host factors. The characterization of host genes that influence both normal cellular processes, as well as susceptibility to tumour induction, is one approach to identifying such factors. Mice carrying two recessive mutations at the *steel* (*Sl*) locus have an environmental defect that affects both normal haematopoietic stem cell function<sup>1,2</sup> as well as susceptibility to Friend leukaemia virus<sup>3-5</sup>. In this study, we have used *Sl/Sl<sup>d</sup>* mice to examine whether malignant transformation by this RNA tumour virus results in a population of cells capable of proliferating even in the defective cellular microenvironment of *Sl/Sl<sup>d</sup>* mice. We report here that late after infection, the leukaemic spleens of Friend virus-infected mice contain cells which, unlike normal haematopoietic stem cells, are able to form macroscopic spleen colonies in irradiated mice of genotype *Sl/Sl<sup>d</sup>*. This observation forms the basis for the first *in vivo* colony assay for leukaemic cells transformed by Friend virus.

Mice carrying two mutant alleles at the *steel* locus (*Sl/Sl<sup>d</sup>*) exhibit pleiotropic defects, including macrocytic anaemia, sterility and defective pigmentation<sup>6</sup>. Transplantation studies have suggested that the haematopoietic defect in these mice is in the cellular microenvironment in which normal haematopoietic stem cells, and more committed erythroid progenitors, proliferate and differentiate. Haematopoietic cell populations from *Sl/Sl<sup>d</sup>* mice contain normal numbers of stem cells, as measured by their ability to form spleen colonies (colony-forming unit-spleen, CFU-S<sup>7</sup>) in irradiated *+/+* littermates. Thus, the *Sl* locus seems to specify a function, presumably involving short-range cell-cell contacts<sup>8,9</sup>, that regulates the ability of pluripotent stem cells to undergo normal erythropoietic differentiation.

Genetically anaemic *Sl/Sl<sup>d</sup>* mice are also highly resistant to spleen focus induction by the polycythaemia- and anaemia-inducing isolates of Friend spleen focus-forming virus<sup>3-5</sup>. The basis for this resistance is unknown. We presented evidence previously that the spleens from *+/+* mice, infected up to 2 weeks previously with Friend virus, did not contain cells capable of spleen colony formation in irradiated *Sl/Sl<sup>d</sup>* mice<sup>4</sup>. Friend leukaemia seems to be a multi-stage disease in which truly malignant cells capable of extensive proliferation do not appear until late in the disease<sup>10,11</sup>. Thus, the failure to observe spleen colonies in secondary *Sl/Sl<sup>d</sup>* recipients early after infection of *+/+* mice could be attributed to either the absence of any leukaemic stem cells in the *+/+* donor spleens or the inability of Friend virus-transformed cells to proliferate in the *steel* environment.

**Fig. 1** Experimental protocols used to study spleen colony forming ability of Friend virus-infected *+/+* spleen cells. Normal WCB F<sub>1</sub> mice of *+/+* genotype (obtained from crossing mice of strains WC/Re-S1/+ and C57BL/6J-+/+*Sl<sup>d</sup>*) were injected intravenously (i.v.) with  $10^3$  focus-forming units (FFU) of SFFV<sub>P</sub> (spleen focus-forming virus contained in preparations of FV-P). SFFV<sub>P</sub> titres were determined in DBA/2J mice by the spleen-focus assay method<sup>22</sup>. At various times after infection, spleens were removed and single-cell suspensions made in Iscove's Modified Dulbecco's Medium (IMDM) and 5% heat-inactivated fetal calf serum. In the first procedure, the spleen cells were injected i.v. into lethally irradiated *+/+* or *Sl/Sl<sup>d</sup>* recipients. (Mice were irradiated immediately before injection using a <sup>137</sup>Cs biological irradiator.) Nine days later the spleens of recipient mice were fixed in Bouin's solution and examined for spleen colonies. In the second procedure, the spleen cells were plated in methylcellulose using a procedure described elsewhere<sup>15</sup>. In brief,  $10^6$  viable nucleated cells per ml were plated in 2.0% methylcellulose in IMDM (containing  $2 \times 10^{-5}$  M 2-mercaptoethanol) plus 30% heat-inactivated fetal calf serum. Large spherical colonies (containing  $2 \times 10^4$ – $1 \times 10^5$  cells) were picked 14 days later. Colonies were pooled and equal numbers of viable nucleated cells were injected i.v. into irradiated *+/+* or *Sl/Sl<sup>d</sup>* mice. Spleens were examined 9 days later.

**Fig. 2** Appearance of spleen colonies formed by Friend leukaemia virus-transformed  $+/+$  spleen cells obtained from *a*, primary leukaemic spleens or *b*, colonies in methyl cellulose derived from a leukaemic spleen. *a*, Viable nucleated spleen cells ( $5 \times 10^6$ ) from a  $+/+$  mouse infected 10 weeks previously with FV-P were injected into irradiated  $+/+$  or  $Sl/Sl^d$  recipients. Spleens were fixed in Bouin's solution 9 days later. The upper spleen, from a  $+/+$  recipient, is confluent with CFU-S colonies. The lower spleen (approximately half of total) is from an  $Sl/Sl^d$  recipient. Sixteen spleen colonies were counted on this spleen section. *b*, Viable nucleated cells ( $2.5 \times 10^5$ ) from the pooled *in vitro* colonies, described in Fig. 1 legend, derived from a  $+/+$  mouse infected 9 weeks previously with FV-P, were injected into irradiated  $+/+$  or  $Sl/Sl^d$  recipients. Spleen colonies were counted 9 days later. 25 colonies were counted on the  $+/+$  recipient spleen and 31 colonies were found on the  $Sl/Sl^d$  recipient spleen.

To examine the influence of the *steel* environment on both the early and late stages of Friend leukaemia, the ability of  $+/+$  spleen cells from Friend virus-infected mice to proliferate and form macroscopic spleen colonies in irradiated  $Sl/Sl^d$  was measured. Two experimental approaches, outlined in Fig. 1, were followed. In the first procedure, spleen cells, derived from the enlarged spleens of  $+/+$  mice infected at various times previously with a clonal isolate<sup>12</sup> of the polycythaemia-inducing strain of Friend leukaemia virus (FV-P), were injected into either irradiated  $+/+$  or  $Sl/Sl^d$  secondary recipients. As shown in Table 1, spleen cells from either normal  $+/+$  mice or  $+/+$  mice infected up to 5 weeks earlier with FV-P did not contain cells capable of spleen colony formation in irradiated  $Sl/Sl^d$  mice, whereas these same cell populations did contain CFU-S capable of forming spleen colonies in irradiated  $+/+$  littermates. These observations agree with previous findings that CFU-S cannot form spleen colonies in  $Sl/Sl^d$  mice<sup>1</sup>, and extend previous observations from this laboratory that, early after infection with FV-P, the spleens of  $+/+$  mice do not contain cells capable of forming spleen colonies in  $Sl/Sl^d$  mice<sup>4</sup>.

**Table 1** Spleen colony formation by Friend leukaemia virus-transformed spleen cells

| Time after infection | No. of spleen cells injected per mouse | No. of spleen colonies $+/+$ recipients | No. of spleen colonies $Sl/Sl^d$ recipients |
|----------------------|--|---|---|
| Uninfected           | $2 \times 10^6$                        | TMTC* (3)                               | 0 (3)                                       |
| 10 days              | $2 \times 10^6$                        | TMTC (3)                                | 0 (12)                                      |
| 5 weeks              | $5 \times 10^6$                        | TMTC (3)                                | 0 (3)                                       |
| 10 weeks             | $5 \times 10^6$                        | TMTC (3)                                | $24 \pm 8$ (3)                              |

Viable nucleated cells from spleens of uninfected  $+/+$  mice or mice infected with FV-P for various times were injected intravenously into lethally irradiated  $+/+$  or  $Sl/Sl^d$  recipients. Spleens were removed 9 days later. The number of recipient spleens examined in each group is enclosed in parentheses. In every case, the spleens of  $+/+$  recipients were confluent with CFU-S colonies.

\* Too many to count.

However, at a later time after infection (10 weeks), the  $+/+$  leukaemic spleens did contain cells that were now able to form macroscopic spleen colonies in irradiated  $Sl/Sl^d$  hosts (Fig. 2*a* and Table 1). Macroscopically, the nodules or colonies formed by  $+/+$  leukaemic spleen cells in irradiated  $Sl/Sl^d$  mice were less diffuse than, and could be easily distinguished from, both smaller FV-P induced spleen foci, and larger CFU-S derived colonies (Fig. 2*a*). In addition, as shown here and previously<sup>1,4</sup>, CFU-S does not form spleen colonies in  $Sl/Sl^d$  hosts, nor can FV-P-infected cells act as infectious centres in an irradiated host. Thus, the colonies observed in the irradiated  $Sl/Sl^d$  mice are derived from a new cell type that only appears very late after infection with FV-P. One such colony, when placed in cell culture, gave rise directly to a permanent cell line. The properties of this cell line are very similar to cell lines derived from leukaemic spleens after subcutaneous injections into syngeneic secondary recipients<sup>13,14</sup>—the cells grow in suspension, resemble immature erythroid cells, and can be induced to synthesize haemoglobin after treatment with dimethyl sulfoxide (data not shown). Thus, spleen colony formation in irradiated  $Sl/Sl^d$  mice by  $+/+$  leukaemic spleens provides an *in vivo* assay system, free of both an infectious centre and CFU-S background, for the enumeration of a new colony-forming cell that results from transformation by Friend leukaemia virus.

These experiments clearly indicate that, late after infection, Friend virus-infected leukaemic spleens contain cells that can proliferate in the defective  $Sl/Sl^d$  environment. However, the relative colony-forming efficiency of these cells in  $+/+$  and  $Sl/Sl^d$  mice is unknown, because of the CFU-S background when  $+/+$  mice are used as hosts (Table 1). Therefore, the second experimental protocol outlined in Fig. 1 legend was followed. In this procedure, spleen cells from  $+/+$  mice infected 9 weeks previously with FV-P were first cloned in a semi-solid methylcellulose medium in the absence of any exogenous conditioning factors. This *in vitro* assay, which is described more fully elsewhere<sup>15</sup>, seems to detect a population of colony-forming cells similar to that detected by the *in vivo*  $Sl/Sl^d$  assay described above. In brief, these *in vitro* colony-forming cells can only be detected in the advanced stages of Friend disease (greater than 3 weeks) and not in uninfected spleens or in spleens early after infection with Friend virus. The cells in the *in vitro* colonies form spleen colonies in irradiated syngeneic hosts, are tumorigenic and a significant proportion can give rise directly to permanent erythroid cell lines<sup>15</sup>. These cell lines can also be chemically induced to synthesize haemoglobin.

As outlined in Fig. 1 legend, *in vitro* colonies derived from the leukaemic spleens of FV-P-infected  $+/+$  mice were pooled and equal numbers of cells injected into either irradiated  $+/+$  or  $Sl/Sl^d$  hosts. As shown in Fig. 2*b*, approximately equal numbers of macroscopic spleen colonies were observed 9 days later in both normal and genetically anaemic littermates. Furthermore, both the size and macroscopic appearance of the spleen colonies were identical in both sets of mice.

To obtain more quantitative data on the relative colony-forming ability of these FV-P-transformed  $+/+$  cells in  $+/+$  and  $Sl/Sl^d$  hosts, varying numbers of cells, from a cell line that had been established in suspension culture for 6 weeks from a primary colony in methylcellulose, were injected into lethally irradiated  $+/+$  or  $Sl/Sl^d$  recipients. As shown in Fig. 3, the spleen colony-forming ability in either host was a linear function of the number of cells injected, with similar slopes in  $+/+$  and  $Sl/Sl^d$  recipients.

The apparent multi-stage nature of the erythroleukaemia induced by Friend virus has been reported<sup>10,11</sup>. The early stage of Friend disease is characterized by a rapid increase in the number of erythroid colony-forming cells<sup>16,17</sup> with limited proliferative capacity, whereas the late stage is associated with the appearance of spleen cells capable of forming solid tumours in secondary recipients or permanent cell lines in culture<sup>11,13,18,19</sup>. Investigation of the cellular relationship between these stages has been difficult due to the lack of a clonal and quantitative assay for these Friend virus-transformed tumour cells. The

**Fig. 3** Spleen colony formation by a Friend leukaemia virus-transformed cell line in irradiated  $+/+$  and  $SI/SI^d$  recipients. The cell line was derived 6 weeks previously from an *in vitro* colony obtained by plating spleen cells from a  $+/+$  mouse infected 10 weeks previously with FV-P. Various numbers of cells were injected i.v. into irradiated  $+/+$  (●) or  $SI/SI^d$  (○) recipients. Nine days later, spleens were fixed in Bouin's solution and spleen colonies counted.

results presented here indicate that irradiated  $SI/SI^d$  mice are suitable hosts for the definitive enumeration of a class of cells with extensive proliferative capacity that only appear quite late after infection with FV-P. The use of  $SI/SI^d$  secondary recipients eliminates any background colonies contributed by CFU-S in the donor spleens. In addition, although virus is released from the  $+/+$  donor spleen cells, use of irradiated secondary recipients eliminates the background of virus-infected spleen foci of host origin<sup>4</sup> which can arise in unirradiated recipients, even those restrictive for viral replication<sup>20,21</sup>. Thus, this quantitative colony assay should facilitate analysis of the relationship between the early and late stages of Friend leukaemia.

That Friend virus-transformed  $+/+$  cells can form spleen colonies with equal efficiency in both  $+/+$  and  $SI/SI^d$  hosts suggests that these erythroleukaemic cells, unlike normal erythroid progenitor cells, are autonomous of the environmental defect in  $SI/SI^d$  mice. However, mutant  $SI/SI^d$  mice are highly resistant to spleen focus and polycythaemia induction by FV-P, indicating that mutation at the *steel* locus can affect at least the early stages of Friend disease. Thus, the observation that Friend virus-transformed  $+/+$  spleen cells can proliferate to form spleen colonies in  $SI/SI^d$  mice raises the intriguing possibility that progression from the early to late stages of Friend leukaemia is accompanied by the appearance of cells with not only extensive proliferative capacity but also autonomy from a genetically defined cellular regulatory factor.

## Interferon suppresses antigen- and mitogen-induced leukocyte migration inhibition

Although first recognized by its effect on virus-cell interactions, interferon (IFN)<sup>1</sup> has a variety of other effects<sup>2</sup>. It can affect cell proliferation<sup>3,4</sup>, modify the immune response at several levels<sup>5</sup>, enhance the cytotoxic action of lymphocytes<sup>6-9</sup>, suppress antibody formation<sup>10</sup> and inhibit the development of delayed-type hypersensitivity (DTH) reactions<sup>11,12</sup>. Therefore we have now tested the effect of interferon on leukocyte migration inhibition (LMI), regarded as the counterpart *in vitro* of DTH in humans<sup>13</sup>. We have found that IFN suppresses both mitogen- and antigen-induced LMI, acting directly on the granulocytes but also affecting the lymphokine production of the lymphocytes.

The agarose microdroplet technique<sup>14</sup> was used in two systems: migration inhibition induced by phytohaemagglutinin (PHA) and LMI of leukocytes from Epstein-Barr virus (EBV)-seropositive donors after exposure to EBV antigens. Washed buffy coat cells ( $20 \times 10^6$ ) were mixed with  $135 \mu\text{l}$  nutrient agarose medium containing an equal volume of  $2 \times \text{RPMI}$  1640 medium, supplemented with 20% FCS or NCS and 0.4% agarose. Droplets ( $2 \mu\text{l}$ ) were placed in migration chambers (Sterilin) and after they had solidified, the chambers were filled with medium, with or without mitogen/antigen and incubated in a  $37^\circ\text{C}$  humidified  $\text{CO}_2$  atmosphere for 18-24 h. After incubation the migration areas were measured and the % migration inhibition (MI) calculated according to the formula

$$\% \text{ MI} = \left[ 1 - \frac{\text{mean migration area with antigen}}{\text{mean migration area without antigen}} \right] \times 100$$

Positive MI was recorded when the % inhibition exceeded 20 in the antigen-induced system and 50 with PHA. Purified PHA (Wellcome),  $1 \mu\text{g ml}^{-1}$ , is known to induce LMI of cells from healthy donors<sup>15,16</sup>. We have previously shown that crude extracts of EBV genome-carrying cells ( $50 \mu\text{g per ml}$  protein) or partially purified EBV-determined nuclear antigen (EBNA),  $10 \mu\text{g ml}^{-1}$ , inhibits the leukocyte migration in EBV-seropositive healthy individuals<sup>17,18</sup>. In this study we used a crude extract of the EBV-producer P3HR-1 line and a partially purified<sup>19</sup> EBNA preparation. Human leukocyte interferon (Hu-IFN- $\alpha^1$ , further IFN) was derived from Namalwa cells induced by Sendai virus<sup>20</sup>. The preparation contained  $2.2 \times$

Fig. 1 Effect of IFN on the migration of buffy coat cells (■, 16 experiments) and separated granulocytes (□, 5 experiments). The results are expressed as mean  $\pm$  s.e.m. migration inhibition; 20% inhibition (horizontal dotted line) can be regarded as significant. (□) represents the mean percentage ( $\pm$  s.e.m.) of dead cells among Ficoll-separated lymphocytes after 24 h cultivation in the presence of various concentrations of IFN.

10<sup>5</sup> U per mg protein. The same batch of IFN was also effective in natural killer cell (NK) boosting experiments<sup>21</sup>.

Figure 1 shows that IFN inhibits leukocyte migration when used in high concentrations (10<sup>4</sup>–10<sup>5</sup> U ml<sup>-1</sup>), probably due to its cytotoxic effect on the lymphocytes, as detected by trypan blue exclusion tests in six experiments. At 100 U ml<sup>-1</sup>, IFN had no significant effect on LMI or detectable cytotoxic effect—the viability of the lymphocytes was 95.8  $\pm$  2.1% after 24 h cultivation.

PHA- and antigen-induced LMI was reduced in the presence of 100 U per ml IFN (Table 1). In the PHA system the mean % MI decreased to 32% compared with 61% in the absence of

IFN. Migration of leukocytes from EBV-seronegative persons was not influenced by EBV-antigen preparations nor by addition of 100 U per ml IFN. The leukocyte migration of EBV-seropositive individuals was inhibited by the two antigen preparations (47% and 44% LMI was induced by the crude P3HR-1 cell extract and by the partially purified EBNA preparation, respectively). Migration inhibition was almost completely abolished in the presence of IFN—this effect was also observed when Hu-IFN- $\alpha$  polypeptide<sup>22</sup>, derived from *Escherichia coli*, was tested in the LMI system<sup>23</sup>.

The direct LMI system is complex: the buffy coat contains both the leukocyte migration inhibitory factor (LIF), producer lymphocytes and the indicator (migrating) granulocytes. To determine whether IFN acted on the lymphocyte and/or granulocyte component, we tested the effect of IFN on the migration of separated granulocytes. IFN at the standard dose used in the mitogen and antigen assays (100 U ml<sup>-1</sup>) was slightly inhibitory (Fig. 1). This result suggests that the IFN-mediated decrease of LMI was not due to stimulation of granulocyte movement. In this system, as in other experiments<sup>16</sup>, 1  $\mu$ g per ml PHA had no direct effect on the granulocyte migration. However, addition of lymphokine-containing supernatant of PHA-stimulated lymphocyte cultures inhibited the migration of separated granulocytes (indirect LMI assay) (Fig. 2).

The supernatant-induced migration inhibition was abolished by adding 100 U per ml IFN during the migration period (mean % MI decreased to 18.3% compared with 42.5% in the absence of IFN) (Table 2). Furthermore, 30 min incubation with IFN before addition of the PHA supernatant had the same blocking effect. In the reversed situation (incubation with IFN 30 min after the addition of PHA supernatant) the supernatant-induced migration inhibition was not abolished. These data indicate that IFN blocks the effect of previously released LIF on the granulocytes. This can be due to competition between LIF and IFN for receptor structures present on the granulocyte membranes. Competition of this type was found to occur between IFN and PHA or other substances (such as cholera and tetanus toxin and certain hormones) when measuring the binding of IFN to cell membrane gangliosides (for review see ref. 24).

The indirect LMI assay (granulocyte migration in the presence of lymphokine-containing supernatants, produced by mitogen-stimulated lymphocytes) was also used to detect the effect of IFN on the lymphocyte component. Untreated and mitomycin-C treated lymphocytes were stimulated with PHA, in the presence and absence of 100 U per ml IFN. The IFN specificity of the effect was tested by adding anti-IFN serum

(provided by K. Cantell). Table 3 shows the results of five experiments. They show that non-proliferating lymphocytes can produce LIF, in analogy with the production of macrophage migration inhibitory factor (MIF)<sup>25</sup>. This precludes the possibility that the IFN-mediated suppression of LMI could be due to its growth-inhibitory effect on the LIF-secreting lymphocytes. In addition, LIF production by both untreated and mitomycin-treated lymphocytes was suppressed by 100 U per ml IFN: 37.6% against 9.2% in the untreated and 31.6% against 8.6% LMI in mitomycin-treated lymphocytes (Table 3). The IFN-induced suppression of LIF production by untreated lymphocytes was completely prevented by the simultaneous addition of anti-IFN serum (37.6% against 9.2%), confirming that IFN itself was responsible for the suppression of LIF production.

Values are % inhibition of migration, those at the base of the columns are mean ± s.e.m.

\* Lymphokine production was induced in blood lymphocytes by PHA stimulation.  $2 \times 10^6$  lymphocytes were resuspended in RPMI 1640 supplemented with 10% FCS. PHA ( $1 \mu\text{g ml}^{-1}$ ) was added to the culture. The LIF-containing supernatant was collected after 36–48 h and tested for its ability to induce LMI on purified granulocytes as previously described. 100 U per ml of IFN were added during the migration period together with the PHA supernatant (column 2), 30 min before or after PHA supernatant addition (columns 3 and 4, respectively).

† Lymphocytes were preincubated with IFN for 30 min.

‡ IFN was added 30 min after start of culture.

Values are % migration inhibition induced on separated granulocytes by lymphocyte culture supernatants, produced in various culture conditions. Values at the base of the columns are mean ± s.e.m.

\* Lymphocytes were incubated with  $25 \mu\text{g ml}^{-1}$  mitomycin-C (Sigma) for 30 min, then the cells were washed thoroughly with medium three times and cultivated for LIF production as described in Table 2.

† 100 U  $\text{ml}^{-1}$  IFN was added during the secretion period.

‡ Anti-(100 U  $\text{ml}^{-1}$ ) IFN antiserum was added simultaneously. Addition of the same amount of antiserum to the migrating granulocytes had no toxic effect (MI was 10.5%, not significantly different from the control). The sheep anti-IFN serum has a titre of  $4.5 \times 10^5$  antiviral units per ml.

**Table 4** Effect of preincubation with IFN or IFN + anti-IFN serum on LIF production of lymphocytes after PHA stimulation

| Donor | -IFN      | +IFN         | +IFN + anti-IFN |
|-------|-----------|--------------|-----------------|
| 1     | 52        | 24           | ND              |
| 2     | 41        | 15           | 44              |
| 3     | 41        | 10           | 36              |
| 4     | 42        | 18           | 32              |
|       | 44 ± 3.09 | 16.75 ± 5.85 | 37.3 ± 4.3      |

The cells were incubated for 30 min with 100 U  $\text{ml}^{-1}$  IFN, with or without simultaneous addition of anti-(100 U  $\text{ml}^{-1}$ ) IFN serum, then washed thoroughly with medium three times and cultivated with  $1 \mu\text{g ml}^{-1}$  PHA-P (see Table 2 for culture conditions). Values are % migration inhibition induced on separated granulocytes, by lymphocyte culture supernatants produced in various culture conditions. Values at the base of the columns are mean ± s.e.m. ND, not detected.

In these experiments IFN was present during the migration period, thus a direct effect on the migrating granulocytes cannot be ruled out. Therefore, in the final experiments lymphocytes were preincubated for 30 min with IFN (with or without anti-IFN serum) and subsequently washed before the PHA-stimulation. The results (Table 4) show that preincubation with 100 U per ml IFN was sufficient to reduce significantly LIF production of PHA-activated lymphocytes (44% MI in the untreated and 16.7% in the IFN-pretreated lymphocytes). The suppression of LMI was prevented by the simultaneous addition of anti-IFN serum (37.3% against 16.7%).

These data suggest that IFN has a direct effect on the granulocytes in the LMI system and that it also blocks LIF production by the activated lymphocytes. This could be due to a direct inhibition of the cellular protein synthesis<sup>26</sup> or due to the activation of suppressor cells<sup>27</sup>. We suggest that the latter mechanism could operate *in vivo*, for example in relation to the immunodepression observed during the acute phase of infectious mononucleosis<sup>16,28</sup>. An IFN-like factor in the serum of acute mononucleosis patients was actually found to block LMI<sup>29</sup>.

This work was supported by contract no. NO1 CP 33316 from the Division of Cancer Cause and Prevention, National Cancer Institute and by grants from the Swedish Cancer Society. R.S. is the recipient of a fellowship from the Swedish Institute, Stockholm. M.M. is the recipient of a fellowship from the foundation Blanceflor Boncompagni-Ludovisi, född Bildt, Stockholm. We thank Professor K. Cantell for the anti-IFN serum.

## Prostaglandin modulation of development of cell-mediated immunity in culture

Kam H. Leung & Enrico Mihich

Department of Experimental Therapeutics, Grace Cancer Drug Center, Roswell Park Memorial Institute, New York State Department of Health, Buffalo, New York 14263

Prostaglandins (PGs) have been implicated as possible modulators of the immune response and various inflammatory processes<sup>1-4</sup>. Various cell components of the immune system are sources of PGs, and mitogen or antigen stimulation of human or murine lymphocytes leads to their enhanced release<sup>5-8</sup>. They are also released from various human and animal tumours<sup>9,10</sup>. Thus, as cells of the immune system are both sensitive to and sources of PGs, these factors may be important as physiological immune regulators. For example, PGs of the E series are capable of inhibiting many effector functions<sup>9-15</sup>. They have also been shown to inhibit the development of the humoral response<sup>16,17</sup>. Although they inhibit the proliferative response to mitogens<sup>18,19</sup>, little is known about their effects on the development of the cell-mediated immune response to antigens. The data summarized here implicate PGs, thromboxane A<sub>2</sub> (TXA<sub>2</sub>) and prostacyclin (PGI<sub>2</sub>) in the regulation of cellular immune responses at the inductive phase. Some of these data have been reported in abstract form<sup>20</sup>.

A dose-response relationship was observed when various numbers of X-ray irradiated P815 mastocytoma cells were cultured with a constant number ( $5 \times 10^6$ ) of allogeneic C57BL/6 spleen cells. The cell-mediated immunity (CMI) was monitored by <sup>3</sup>H-thymidine incorporation and anti-target cell lytic activity (% of specific <sup>51</sup>Cr release) on day 4 in culture. The <sup>3</sup>H-thymidine incorporation into unstimulated lymphocytes was  $1,664 \pm 801$  c.p.m. and increasing the number of stimulator cells from  $1 \times 10^5$  to  $5 \times 10^5$  led to an increase in both <sup>3</sup>H-thymidine incorporation ( $8,576 \pm 3,928$  to  $61,998 \pm 14,079$  c.p.m.) and cytotoxic activity (% specific <sup>51</sup>Cr release  $22.7 \pm 7.7$  to  $52.5 \pm 6.8$ , effector: target cell (E:T) = 50:1). A further increase of stimulator cells to  $1 \times 10^6$  decreased the levels of both these parameters to those of the unstimulated culture. The <sup>3</sup>H-thymidine uptake into the cells was only a measure of the proliferation of the lymphocytes after antigenic stimulation. The ultimate proof of immunological significance of the stimulation is the production of cytolytic effector cells.

Table 1a shows that addition of PGE<sub>1</sub> or PGE<sub>2</sub> on day 0 of culture had an inhibitory effect on <sup>3</sup>H-thymidine incorporation on day 4 of culture. At this time the response was maximal. The <sup>3</sup>H-thymidine incorporation into the lymphocytes was 24% and 38% of the control in the presence of 30 nM PGE<sub>1</sub> and 30 nM PGE<sub>2</sub>, respectively. The agents at these concentrations had no effect on the unstimulated lymphocytes or on the <sup>3</sup>H-thymidine incorporation when added at the time of assay. As indicated by the <sup>51</sup>Cr release assay (Table 1b), 30 nM of PGE<sub>1</sub> or PGE<sub>2</sub> inhibited the development of the CMI by 50%. PGE at the concentrations tested had no effect on the lytic activity of effector cells generated *in vitro* when added at the time of the <sup>51</sup>Cr release assay. This lack of activity on *in vitro*-generated effector cells compared with the effect on *in vivo*-generated effector cells has recently been reported<sup>15</sup>. The concentration of PGE found in inflammatory fluid<sup>7</sup> and in mitogen- or antigen-stimulated cultures<sup>5,6</sup> is in the range of 3–300 nM. Thus, the finding that 30 nM PGE<sub>1</sub> or PGE<sub>2</sub> could inhibit sensitization of lymphocytes is consistent with the hypothesis that, at physiological levels, these agents act as negative-feedback regulators.

Kinetic experiments indicated that PGE<sub>1</sub> affects only the magnitude of the CMI and does not cause a shift in the responses. When PGE<sub>1</sub> was added at various intervals after culture initiation, it was found to act during the inductive phase of the immune response. PGE<sub>1</sub> was active when added to spleen cells as long as 20 h before and up to 24 h after the addition of stimulator cells, but when added 48 h after culture initiation, it was not effective. It has recently been reported that if human peripheral blood lymphocytes are cultured for 24 h before being stimulated by phytohaemagglutinin, their proliferation is no longer inhibited by PGs<sup>21</sup>. However, this study shows that the antigenic stimulation of murine spleen lymphocytes which had been preincubated for 20 h, can still be modulated by PGE<sub>1</sub>. In separate experiments, when PGE<sub>1</sub> was in spleen cell culture for 20 h and was removed by washing before the addition of stimulator cells, little inhibition was observed (data not shown). Thus, these data indicate the reversibility of the effect and the fact that PGE<sub>1</sub> seems to have a relatively long half life in spleen cell cultures. The effect of PGE<sub>1</sub> was also negated if the agent was removed by washing the cells within 8 h after initiation of the culture. By 48 h the effect of PGE<sub>1</sub> was irreversible. In summary, the effects of PGE on the CMI response affect the early period of the induction phase of the response.

The results shown in Fig. 1 indicate that indomethacin, an irreversible inhibitor of cyclooxygenase, the enzyme that catalyses the conversion of arachidonic acid to the endoperoxides PGG<sub>2</sub> and PGH<sub>2</sub> (which are common intermediates for TXA<sub>2</sub>, PGE<sub>2</sub>, PGF<sub>2 $\alpha$</sub> , PGI<sub>2</sub> and other PGs)<sup>22</sup>, augmented

**Fig. 1** Effect of indomethacin and Ro 20-5720 on the development of the CMI. *a*, Thymidine incorporation; *b*, cytotoxicity. The results were expressed in terms of the non-drug-treated control normalized to 100. The control values for the thymidine incorporation for indomethacin and Ro-5720 were  $7,372 \pm 1,370$  and  $15,341 \pm 3,115$  c.p.m., respectively. The control values for <sup>51</sup>Cr release were  $24.3 \pm 3.2$  and  $23.4 \pm 2.6$  c.p.m., respectively. Each value represents the mean % of control  $\pm$  s.d. ( $n=4$ ). \*  $P < 0.005$ , \*\*  $P < 0.001$  and \*\*\*  $P < 0.001$ .

Primary immunization cultures with C57BL/6 mouse spleen cells as responder cells and P815 tumour cells as stimulator cells were established according to published procedures<sup>30</sup>. Briefly, cultures were maintained in RPMI 1640 medium supplemented with 2 mM L-glutamine, 25 mM HEPES (pH 7.45),  $3 \times 10^{-5}$  M mercaptoethanol, 10% heat-inactivated fetal calf serum (FCS, Gibco), 100  $\mu$ g ml<sup>-1</sup> streptomycin, 100 U ml<sup>-1</sup> penicillin and 100  $\mu$ g ml<sup>-1</sup> gentamycin. A suspension of  $5 \times 10^6$  cells in 1.9 ml of supplemented medium was added to 35-mm tissue culture dishes and the cells were incubated at 37 °C in a 5% CO<sub>2</sub> atmosphere. Stimulator cells were X-ray irradiated (4,000R, P815x cells) and test agents were added in 0.1 ml medium to the spleen cell suspension. In some cases, 95% ethyl alcohol (EtOH) was used as initial solvent, but the final concentration did not exceed 0.01% which was shown not to affect the assays. The same volume of medium was added to control cultures. In these conditions, the cytotoxicity of effector cells (E) that developed was proportional to the number of stimulating cells which were varied from  $5 \times 10^5$  to  $2.5 \times 10^6$ . To measure thymidine incorporation, microcultures were incubated in flat-bottom Microtest plates (Linbro) at 37 °C and 5% CO<sub>2</sub> in air. The microcultures consisted of 0.1 ml cell suspension from day 4 culture and 0.1 ml of RPMI medium and 50  $\mu$ l (1  $\mu$ Ci) of [ $Me$ - $^3H$ ]thymidine (specific activity 6.7 Ci mmol<sup>-1</sup>). After 4 h the cultures were collected on glass filter strips with an automatic cell collector. The filters were washed with saline. They were dried and counted in scintillation fluid in a Beckman scintillation counter. *In vitro* effector cells were collected after day 4 and unless otherwise stated, were centrifuged, washed and resuspended in 0.5 ml of medium supplemented with 5% FCS. Cell viability was determined by trypan blue exclusion and was unaffected by the drug treatments. The density of viable effector cells was adjusted to  $1 \times 10^7$  cells ml<sup>-1</sup>.  $^{51}Cr$ -labelled P815 target cells (T) were prepared according to published procedures<sup>31</sup>, and their cell density adjusted to  $2 \times 10^5$  cells ml<sup>-1</sup>. Labelled target cells ( $2 \times 10^4$ ) in 0.1 ml were added to 0.1 ml of effector cells in duplicate 12  $\times$  75-mm plastic tubes (Falcon). The number of effector cells was adjusted to give different E:T ratios—50:1, 25:1 and 12.5:1. The preparations were incubated for 4 h at 37 °C in a humidified CO<sub>2</sub> incubator and the reaction was stopped by adding 2 ml of cold RPMI 1640 medium. The percentage release of radioactive chromium was calculated as follows:

$$\% ^{51}Cr \text{ release} = \frac{\text{c.p.m. in supernatant}}{\text{c.p.m. in supernatant} + \text{c.p.m. in pellet}} \times 100$$

The per cent specific  $^{51}Cr$  release is obtained by subtracting the %  $^{51}Cr$  released from labelled targets in the presence of nonensitized spleen cells from the value obtained in the presence of sensitized spleen cells. All experiments have been reproduced at least twice.

\* Spleen lymphocytes ( $5 \times 10^6$ ) were cultured with  $5 \times 10^5$  P815x cells for 4 days.

<sup>†</sup> These values represent the mean  $\pm$  s.d. where  $n = 3$ .

<sup>‡</sup> The final concentration of either PGE<sub>1</sub> or PGE<sub>2</sub> added at the time of initiation of the culture.

<sup>§</sup> The numbers in parentheses represent per cent of control without PG.

<sup>||</sup> The statistical significance which was determined by the Student's two-tailed *t*-test is indicated by: <sup>§</sup>,  $P < 0.05$ ; <sup>†</sup>,  $P < 0.01$ ; and <sup>\*</sup>,  $P < 0.001$ .

<sup>††</sup> Prostaglandins were added at the time of assay on day 4. ND, not done.

$^3H$ -thymidine incorporation and lytic activity in a concentration-dependent manner. The optimal concentration was  $3 \times 10^{-7}$  M (0.1  $\mu$ g ml<sup>-1</sup>). Ro 20-5720 (*d*,1-6-chloro- $\alpha$ -methyl-carbazole-2-acetic acid), a reversible inhibitor of cyclooxygenase<sup>17</sup>, also augmented the CMI (optimal concentration  $10^{-8}$  M). Inhibitors of PG biosynthesis have been extensively studied (for a recent review, see ref. 23). Inhibitors of cyclooxygenase have been shown previously to inhibit tumour

growth<sup>16</sup>, enhance humoral responses<sup>17</sup> and augment mitogen- or antigen-induced blastogenesis<sup>18,19</sup>.

In addition to the PGs, PGI<sub>2</sub> and TXA<sub>2</sub> are also released by macrophages and lymphocytes<sup>2,23-25</sup>. PGI<sub>2</sub> ( $3 \times 10^{-4}$  M) inhibited the cytolytic activity of effector cells from immunized mice by 20% ( $P < 0.02$ ), whereas at concentrations from  $3 \times 10^{-10}$  M to  $3 \times 10^{-6}$  M it showed no effect on the development of the CMI in culture. This lack of activity may be due to the short

**Table 2** Effects of exogenous PGE<sub>2</sub> on the CMI in the presence or absence of inhibitors of prostaglandin synthesis

Spleen cell cultures were exposed to  $3.5 \times 10^5$  P815x cells and indomethacin, imidazole, tranylcypromine or PGE<sub>2</sub> alone or in the indicated combinations.

\* The results were expressed as per cent of non-drug-treated control culture response. The control values for thymidine incorporation and % specific <sup>51</sup>Cr release were  $40,197 \pm 14,977$  and  $49.5 \pm 5.7$  (E:T ratio 50:1), respectively. Each value represents the mean % of control of four experiments  $\pm$  s.d.

<sup>†</sup>  $P < 0.05$ , <sup>‡</sup>  $P < 0.01$ , <sup>§</sup>  $P < 0.001$ .

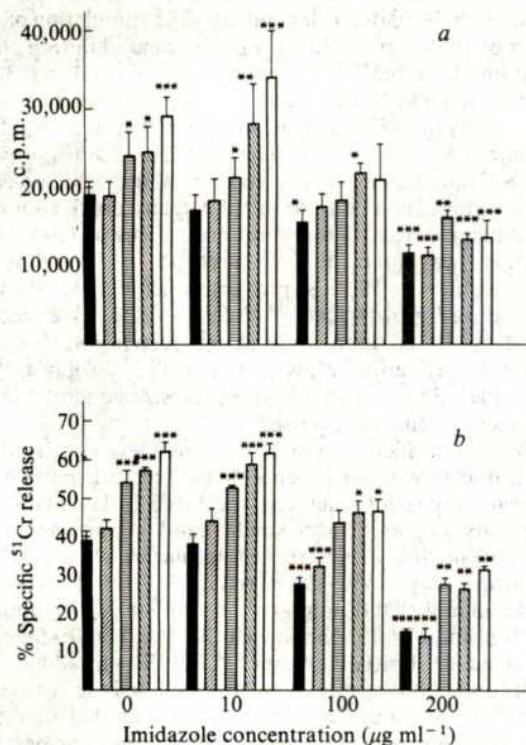

half life of PGI<sub>2</sub> ( $t_{1/2} = 3-5$  min) in culture conditions<sup>26</sup>. The half life of TXA<sub>2</sub> is also extremely short ( $t_{1/2} = 30$  s)<sup>27</sup>. Knowing these facts, tranylcypromine, an inhibitor of PGI<sub>2</sub> synthetase (ID<sub>50</sub> concentration  $160 \mu\text{g ml}^{-1}$ )<sup>26</sup> and imidazole, an inhibitor of thromboxane synthetase (ID<sub>50</sub> concentration  $8 \text{ mM}$ )<sup>27,28</sup>, were tested to assess their effect on the CMI. Note that the effects of these two agents are specific for the respective enzymes and that at the concentrations tested here they do not affect other enzymes of arachidonic acid metabolism. That they may affect other enzyme systems cannot be ruled out. In fact, imidazole is known to stimulate phosphodiesterase<sup>28</sup> and such stimulation reduces cyclic AMP pools and results in either no effect or augmented CMI development (K.H.L., unpublished

results). The data (Fig. 2) show that imidazole (ID<sub>50</sub>  $3 \text{ mM}$  or  $200 \mu\text{g ml}^{-1}$ ) inhibited the development of the CMI whereas tranylcypromine ( $0.2 \text{ mM}$  or  $25 \mu\text{g ml}^{-1}$ ) augmented it in a concentration-dependent manner. When used in combination, imidazole and tranylcypromine were antagonistic in their effect on the CMI. There is, however, an apparent constant minimal per cent reduction of the CMI caused by imidazole regardless of the concentration of tranylcypromine used, and similarly, the augmentation with tranylcypromine in the presence of different concentrations of imidazole remains constant at a certain minimal level. This may reflect the fact that a blockage of TXA<sub>2</sub> synthesis by imidazole leads to a lower TXA<sub>2</sub> pool, but also a consequence of this blockage could be increased synthesis of PGI<sub>2</sub> and PGE<sub>2</sub>. In the presence of imidazole, the effect of tranylcypromine is less effective and vice versa. This may suggest that, apart from inhibition of PGI<sub>2</sub> synthesis by tranylcypromine, some of the action may be due to the possible increased production of TXA<sub>2</sub>.

Table 2 summarizes the effects of exogenous PGE<sub>2</sub> on the CMI in the presence or absence of inhibitors of PG synthesis. The effect of indomethacin was reversible by PGE<sub>2</sub>, indicating that PGE<sub>2</sub> is a negative mediator of the CMI development. The effects of imidazole and PGE<sub>2</sub> were additive. However,  $3 \text{ nM}$  of PGE<sub>2</sub> did not effectively reverse the augmented CMI resulting from the addition of tranylcypromine. More interestingly, the effect of tranylcypromine on the <sup>3</sup>H-thymidine incorporation was abrogated by  $30 \text{ nM}$  of PGE<sub>2</sub>, but its effect on the cytotoxic activity was not completely reversed ( $P < 0.01$ ). This may suggest that PGE<sub>2</sub> is less effective in reversing the action of TXA<sub>2</sub> in the presence of a lower level of PGI<sub>2</sub> and TXA<sub>2</sub>; PGE<sub>2</sub> or PGI<sub>2</sub> may be affecting different subsets of lymphocytes. In the presence of imidazole and tranylcypromine, the effect of PGE<sub>2</sub> was, as in the presence of indomethacin, due to the lower PGI<sub>2</sub> and TXA<sub>2</sub> pools. This seems to indicate that PGI<sub>2</sub> and TXA<sub>2</sub> are more potent than PGE<sub>2</sub> in modulating the development of CMI.

Three implications may be derived from these results: (1) PGI<sub>2</sub> may be a negative (inhibitory) regulator and TXA<sub>2</sub> a positive (augmentative) regulator of the CMI development. (2) Augmentation of the CMI by tranylcypromine may be a consequence of the removal of PGI<sub>2</sub> or of a channelling of PGH<sub>2</sub> into TXA<sub>2</sub> and other PGs. The converse of this argument may be applied to explain the lower CMI response following inhibition of TXA<sub>2</sub> synthesis by imidazole. (3) The relative concentrations of PGI<sub>2</sub>, TXA<sub>2</sub> and PGs may determine the magnitude of the immune response.

We thank Mrs M. J. Ehrke for helpful discussions, Dr J. E. Pike (Upjohn) for PGI<sub>2</sub>, Dr W. E. Scott (Hoffman-LaRoche) for Ro 20-5720, and Ms P. Dickens and K. M. Schrader for preparation of the manuscript. This work fulfilled part of the requirement for the PhD degree of K.H.L.

**Fig. 2** Effect of imidazole or tranylcypromine alone or in combination on the development of the CMI. *a*, Thymidine incorporation; *b*, cytotoxicity. The results were expressed as mean  $\pm$  s.d. ( $n = 4$ ). \*,  $P < 0.005$ , \*\*,  $P < 0.01$  and \*\*\*,  $P < 0.001$ . The concentrations of tranylcypromine were: ■,  $0 \mu\text{g ml}^{-1}$ ; □,  $1 \mu\text{g ml}^{-1}$ ; ▨,  $5 \mu\text{g ml}^{-1}$ ; ▩,  $10 \mu\text{g ml}^{-1}$ ; and ▤,  $25 \mu\text{g ml}^{-1}$ .

**Prostacyclin (PGI<sub>2</sub>), an unstable metabolite of arachidonic acid synthesized by vascular endothelial and smooth muscle cells, is a potent vasodilator and endogenous inhibitor of platelet aggregation<sup>1–10</sup>. Regulation of PGI<sub>2</sub> synthesis by the vessel wall is not well understood<sup>11–16</sup>. We have investigated the possibility that a product released from platelet granules during degranulation might modify vessel wall PGI<sub>2</sub> biosynthesis. We report here that a non-dialysable, platelet-dependent factor in serum dramatically stimulates PGI<sub>2</sub> synthesis by cultured bovine aortic endothelium, aortic smooth muscle, and adrenal capillary endothelium. Platelet-derived growth factor (PDGF), a releasable peptide contained within platelet alpha granules<sup>17–20</sup>, stimulates PGI<sub>2</sub> synthesis by the above cell types as much as 100-fold. The concentrations of PDGF required to produce these effects are below the level reported in normal human serum<sup>18</sup>. We postulate that *in vivo* released PDGF may increase vessel wall PGI<sub>2</sub> production as part of a negative feedback mechanism controlling platelet aggregation.**

† To whom correspondence should be addressed.

Endothelial cells were cultured from bovine aorta by a modification of previously published techniques (see legend to Table 1)<sup>21–23</sup>. These cells formed confluent monolayers and exhibited light-microscopic and ultrastructural characteristics consistent with endothelium<sup>24–26</sup>. They also contained the endothelial cell marker factor VIII antigen<sup>24</sup>: immunofluorescent studies revealed specific granular staining concentrated in the perinuclear region (anti-bovine factor VIII provided by J. Brown, University of California, San Diego). Bovine aortic smooth muscle cells were cultured as described elsewhere<sup>27</sup>. These appeared spindle-shaped, grew in multilayers with the characteristic 'hill and valley' pattern, and contained prominent myofilamentous bundles characteristic of smooth muscle. Culture and characterization of bovine adrenal capillary endothelium has been reported elsewhere<sup>28</sup>. The capillary endothelial cells used in this study were cloned from single cells and used between passages eight and twelve. Bovine aortic endothelial and smooth muscle cell cultures between passages one and five were used.

Cells in culture were incubated with vehicle or treatment as described in Table 1. Of the total cyclo-oxygenase products made in culture, aortic endothelium made 95% 6-keto prostaglandin F<sub>1α</sub> (6 KF<sub>1α</sub>), capillary endothelium 80%, and aortic smooth muscle 73% 6 KF<sub>1α</sub>. In descending order, lesser amounts of PGF<sub>2α</sub>, PGE<sub>2</sub>, PGD<sub>2</sub> and thromboxane B<sub>2</sub> (TXB<sub>2</sub>) were also made. For comparison, aortic strips *in vitro* made about 96% 6KF<sub>1α</sub> and brain microvessels made 80% (ref. 29).

Serum has been reported to stimulate prostaglandin synthesis by MC5-5 fibroblasts in culture<sup>30</sup>. In preliminary experiments we demonstrated that human or bovine serum also potently stimulated prostaglandin and prostacyclin synthesis in cells of vascular origin, bovine aortic endothelium and smooth muscle. To assess the platelet's contribution to this activity, platelet-rich plasma-derived serum (PRS) and platelet-poor plasma-derived serum (PDS) were prepared (see Table 1) and tested for their ability to stimulate PGI<sub>2</sub> synthesis in culture. The data shown in Table 1 indicate that at least 80% of the stimulatory activity of serum seems to be platelet-dependent. (The stimulation of PGI<sub>2</sub> synthesis by PDS may be due to PDGF released during plasma preparation, thrombin<sup>31</sup>, bradykinin, angiotensin II (ref. 32), or other as yet unidentified compounds.) Preparations with higher specific activity than PRS have been obtained by heating (100 °C for 2.5 min) and extracting platelets into 1.0 M NaCl. (Specific activity is defined as ng 6KF<sub>1α</sub> accumulated per mg of added protein<sup>33</sup>.) These data point to the platelet as a major source of PGI<sub>2</sub>-stimulating activity found in serum. This platelet-dependent activity was nondialysable, stable at 56 °C, and at least partially stable at 100 °C—properties similar to those of platelet-derived growth factor<sup>17</sup>. Because PDGF was recently proposed as the component in serum responsible for phospholipase A<sub>2</sub> activation in Swiss mouse 3T3 fibroblasts<sup>34</sup>, the ability of PDGF to stimulate PGI<sub>2</sub> synthesis in endothelial and smooth muscle cells was assessed.

PDGF was purified<sup>17</sup> from human platelets and incubated with cultured bovine aortic endothelial, smooth muscle, and adrenal capillary endothelial cells (see Table 2). The PDGF used in this study migrated as a single band on polyacrylamide electrophoresis with an apparent molecular weight of 35,000 in non-reducing conditions—after reduction with 5% (v/v) 2-mercaptoethanol PDGF migrated as two bands with apparent MW 13,000 and 17,000. As shown in Table 2, PDGF stimulated dose-dependent biosynthesis of PGI<sub>2</sub>. When added at a concentration of 8.0 ng ml<sup>-1</sup>, PDGF stimulated the synthesis of PGI<sub>2</sub> by 74-, 84- and 15-fold in aortic endothelial, smooth muscle, and capillary endothelial cell cultures, respectively. Followed over a 24-h period, 6KF<sub>1α</sub> accumulated in an essentially linear manner in these cultures. To evaluate the reversibility of PDGF action, cultures were washed five times with 2.5 ml M199 after incubation for 6 h with PDGF (8 ng ml<sup>-1</sup>) and the medium replaced with M199 plus vehicle only. After washing, the rate of 6KF<sub>1α</sub> accumulation returned to that of the unstimulated cultures. Thus, PDGF-induced stimulation

required the continued presence of PDGF in the medium. Similar results were obtained with PRS. In addition to stimulating PGI<sub>2</sub> synthesis, PDGF stimulated PGF<sub>2α</sub> synthesis by the above cell types, with a similar dose response. This suggests that PDGF increases prostaglandin production either by stimulating the cyclo-oxygenase, or, more likely, by increasing arachidonate availability to the cyclo-oxygenase through increasing phospholipid deacylation. In fact, PDGF activation of phospholipase A<sub>2</sub> has recently been reported<sup>34</sup>. Serum stimulates prostaglandin synthesis in a similar manner in these and other cells<sup>30,34</sup>.

Table 1 Platelet-dependent stimulation of PGI<sub>2</sub> synthesis

|  | Control                  | PRS                      | PDS                       |

Platelet-rich plasma derived serum (PRS) and platelet-poor plasma-derived serum (PDS) were incubated with vascular cells in culture as described below. Bovine aortic endothelial cells were cultured by a modification of existing techniques<sup>21-23</sup>. Briefly, descending thoracic aortas were excised aseptically from week-old calves within 15 min of death and transported in calcium-magnesium-free Dulbecco's phosphate-buffered saline (PBS) with antibiotics (ABX) (penicillin 50 µg ml<sup>-1</sup>, streptomycin 50 µg ml<sup>-1</sup>, neomycin 100 µg ml<sup>-1</sup> and tylocine 60 µg ml<sup>-1</sup>). The adventitia was removed, the lumen washed with 500 ml of PBS, the intercostals and distal end clamped and the lumen filled with 1 mg ml<sup>-1</sup> collagenase (Worthington Biochemical, 135 U per mg) in Hank's balanced salt solution (Gibco). With the proximal and distal ends occluded, the vessel was incubated by immersion in PBS at 37 °C for 20 min. The collagenase solution was collected, the lumen washed gently four times with culture medium and the washes and collagenase solution were pooled and spun at 100g for 5 min. The pellet was resuspended in culture medium and plated on tissue culture dishes pretreated with gelatin<sup>24</sup> and fibronectin (Collaborative Research) at 1 µg per cm<sup>2</sup>. Culture medium consisted of 1:1 mixture of alpha MEM and Dulbecco's modified Eagle's medium (Gibco) with 20% calf serum (Microbiological Associates), 2 mM added L-glutamine, 25 µg ml<sup>-1</sup> endothelial cell growth supplement (Collaborative Research) and ABX. Bovine aortic smooth muscle and adrenal capillary endothelial<sup>27,28</sup> cells were plated 48 h before the start of an experiment at 1–4 × 10<sup>5</sup> cells per 35 mm tissue culture dish in the appropriate growth conditions for each cell type. At the start of each experiment, the plates were washed twice with 2.5 ml of M199 (Medium 199 (Gibco) with 2 mM added L-glutamine), 2.5 ml of M199 plus vehicle or treatment and the plates returned to the incubator (5% CO<sub>2</sub>/95% air, 37 °C) for the time required. After incubation, the medium was removed and transferred to tubes containing indomethacin (final concentration 4 µM) and frozen until required for assay. Cell numbers were determined using a Coulter Counter (Coulter Electronics) after washing with PBS, briefly treated with trypsin-EDTA solution (Gibco), and suspended in 2% formaldehyde in PBS. PGI<sub>2</sub> and TXA<sub>2</sub> synthesis was assessed by measuring the accumulated levels of their respective stable products<sup>15</sup>, 6KF<sub>1α</sub> and TXB<sub>2</sub>. PGF<sub>2α</sub>, PGE<sub>2</sub>, PGD<sub>2</sub>, TXB<sub>2</sub> and 6KF<sub>1α</sub> concentrations were determined by radioimmunoassay of the incubation medium using techniques described elsewhere<sup>15</sup>. The specificity of this assay system is such that results obtained by direct radioimmunoassay (RIA) of the incubation media are similar to those obtained by first separating the prostaglandins in the media by high performance liquid chromatography and then measuring each fraction by RIA<sup>29,37</sup>. PRS and PDS were prepared by a modification of published techniques<sup>20</sup>. Blood was drawn by venipuncture from normal volunteers into 1/10 volume 3.82% sodium citrate. The anticoagulated whole blood was spun at 100g for 20 min, the platelet-rich plasma (PRP) collected and divided into two portions. One half was clotted by the addition of 1 M CaCl<sub>2</sub> (1 ml per 50 ml PRP) followed by incubation for 3 h at 37 °C. The rest was spun at 2,000g for 15 min, the supernatant collected and the platelet pellet resuspended in 1 M NaCl for future extraction. The supernatant was further spun at 20,000g for 30 min to remove any residual platelets, then clotted with CaCl<sub>2</sub> as above. The resulting PRS and PDS were allowed to stand at 4 °C overnight, centrifuged at 20,000g for 30 min, dialysed (MW cutoff 3,000) against 500 volumes of 145 mM NaCl, 4 mM KCl, 3 mM CaCl<sub>2</sub>, and 1.5 mM MgCl<sub>2</sub>, measured out and frozen for later use. Serotonin was measured in pre-dialysed samples of PRS and PDS by liquid chromatography with electrochemical detection<sup>28</sup> as an index of platelet degranulation. Serotonin levels in the PRS and PDS used in this study were >700 nM and <1 nM, respectively. 500 µl of PRS or PDS were added directly to culture dishes containing 2.0 ml of M199. Twenty-four hour incubations were carried out and culture fluids assayed. 6KF<sub>1α</sub> was not detectable in the dialysed PRS or PDS. Indomethacin (4 µM) inhibited 6KF<sub>1α</sub> synthesis in all cultures by over 99%. Data were analysed by one-way analysis of variance, multiple comparisons were made by the significant difference method<sup>39</sup>. Values shown are mean ± s.e.m. (n = 5). Both PRS and PDS stimulated PGI<sub>2</sub> biosynthesis by bovine aortic endothelial and smooth muscle cells, but PDS was at least five times less active in this capacity. Full recovery of PGI<sub>2</sub> stimulating activity was achieved by recombining platelets and platelet-poor plasma before clotting. Means with different superscripts were significantly different (P < 0.01).

Table 2 PDGF stimulates PGI<sub>2</sub> synthesis

| Cell type                | PDGF<br>(ng ml <sup>-1</sup> ) | 6KF <sub>1α</sub><br>(ng ml <sup>-1</sup> ) | Cell number per plate<br>(×10 <sup>-5</sup> ) |

|                          | 0.25                           | 0.045 ± 0.001 <sup>1</sup>                  | 4.60 ± 0.32                                   |
|                          | 0.80                           | 0.059 ± 0.010 <sup>1</sup>                  | 4.81 ± 0.29                                   |
|                          | 2.53                           | 0.213 ± 0.018 <sup>2</sup>                  | 4.30 ± 0.51                                   |
|                          | 8.00                           | 0.813 ± 0.059 <sup>3</sup>                  | 5.30 ± 0.78                                   |

Platelet PDGF was purified<sup>17</sup>, added to 1 M NaCl in polypropylene tubes and frozen for later use. PDGF was thawed immediately before use, diluted, if necessary, in 1 M NaCl, and added to 35 mm culture vessels containing 2.5 ml M199. Controls received 25 µM NaCl per plate, the maximum amount of NaCl added to any PDGF-treated culture. This amount of NaCl did not affect prostaglandin production. Twenty-four hour incubations were carried out and culture fluids assayed as described in the text. Prostaglandins were not detected in culture fluid from plates incubated with PDGF (8.0 ng ml<sup>-1</sup>) without cells. Indomethacin inhibited PDGF-stimulated PGI<sub>2</sub> synthesis by 99.8%. Data were analysed as described in the legend to Table 1. Means with different superscripts were significantly different (P < 0.01). Values shown are mean ± s.e.m. (n = 4).

As shown in Table 2, the well known mitogenic effects of PDGF were observed with smooth muscle cells but not with aortic or capillary endothelium. The prostacyclin-stimulating activity of PDGF, however, was seen with all three cell types. Thus the effects of PDGF on arachidonic acid metabolism were not always associated with its effects on cell division.

Thus both a platelet-dependent factor in serum and PDGF stimulate PGI<sub>2</sub> synthesis by vascular cells in culture. Both factors (1) appear to be platelet-derived; (2) are non-dialysable and at least partially heat stable (100 °C for 2.5 min); (3) stimulate cultures with a similar time course (linear 6KF<sub>1α</sub> accumulation over 24 h); (4) act reversibly, and (5) stimulate PGI<sub>2</sub> synthesis most likely by increasing arachidonate availability for cyclo-oxygenase. We therefore suggest that PDGF may be the factor responsible for the platelet-dependent stimulation of PGI<sub>2</sub> synthesis by PRS. The level of PDGF reported in whole human serum is approximately 50 ng ml<sup>-1</sup> (ref. 18), well above the concentrations needed to stimulate PGI<sub>2</sub> synthesis *in vitro* in the present study. Thus PDGF may act locally to increase vascular PGI<sub>2</sub> production after its release *in vivo* at a site of platelet degranulation, as part of a negative feedback mechanism controlling platelet aggregation.

Many applications envisioned for liposomes in cell biology and chemotherapy require their direction to specific cellular targets<sup>1–3</sup>. The ability to use antibody as a means of conferring specificity to liposomes would markedly increase their usefulness. We report here a method for covalently coupling soluble proteins, including monoclonal antibody and *Staphylococcus aureus* protein A (ref. 4), to small sonicated liposomes, by using the heterobifunctional cross-linking reagent *N*-hydroxysuccinimidyl 3-(2-pyridyldithio)propionate (SPDP, Pharmacia). Liposomes bearing covalently coupled mouse monoclonal antibody against human  $\beta_2$ -microglobulin [antibody B1.1G6 (IgG2a,  $\kappa$ ) (B. Malissen *et al.*, in preparation)] bound specifically to human, but not to mouse cells. Liposomes bearing protein A became bound to human cells previously incubated with the B1.1G6 antibody, but not to cells incubated without antibody. The coupling method results in efficient binding of protein to the liposomes without aggregation and without denaturation of the coupled ligand; at least 60% of liposomes bound functional protein. Further, liposomes did not leak encapsulated carboxyfluorescein (CF) as a consequence of the reaction.

Reaction of SPDP with molecules containing primary amino groups results in the introduction of dithiopyridyl groups through the formation of amide bonds and release of *N*-hydroxysuccinimide<sup>5</sup>. Protein-bound dithiopyridine (DTP) can be readily activated as the thiol derivative by reduction with

**Table 1** Precipitation of protein-bearing liposomes by *S. aureus* strain Cowan I (SaCI)

| Determination                     | <sup>125</sup> I-labelled protein on liposomes:<br>B1.1G6 | Protein A |
|-----------------------------------|---|-----------|
| <sup>125</sup> I-labelled protein | 66%   | 3%        |
| CF in liposomes                   | 62%   | ~10%      |

<sup>125</sup>I-labelled protein-bearing liposomes (20  $\mu$ l, from fraction 8 of the Sepharose 4B column chromatography) were mixed with 1% bovine serum albumin in buffered saline in duplicate 900- $\mu$ l volumes. To some tubes 100  $\mu$ l of 10% SaCI was added; to control tubes only medium was added. After 30 min at 4 °C, tubes were spun 15 min at 2,300g to precipitate the SaCI and bound liposomes. Values represent the % liposomes bound to SaCI, as measured by <sup>125</sup>I counts in the bacterial pellet, and by release of fluorophore by addition of Triton.

dithiothreitol in mild conditions (acidic pH). These thiolated proteins can be reacted with other DTP-substituted molecules to produce covalently coupled products in conditions where homopolymerization and intramolecular cross-linking are kept to a minimum. For coupling of proteins to liposomes we have reacted SPDP with phosphatidylethanolamine (PE) in organic solvent, to form the stable derivative PE-DTP. This compound can be mixed with phosphatidylcholine and cholesterol, and liposomes formed by sonication. Protein containing activated thiol groups can then be coupled.

Figure 1 shows fractions eluted from a small Sepharose 4B column following coupling reactions between liposomes containing 4% PE-DTP and thiolated B1.1G6 (Fig. 1a, b), or thiolated protein A (Fig. 1c, d). Counts of <sup>125</sup>I-labelled protein are seen in the void volume for both proteins (Fig. 1a, c) only when liposomes were present. Figure 1 also shows control incubations of <sup>125</sup>I-labelled proteins incubated alone. In reactions carried out with <sup>14</sup>C-labelled lipid and unlabelled protein (Fig. 1b, d) it can be seen that the liposome peak corresponds to the position of elution of protein in the void volume. This peak is also shown by fluorescence. Due to the high initial concentration of CF (40 mM), the encapsulated CF is strongly quenched<sup>6–8</sup>, but the quenching can be relieved by the addition of detergent. The marked increase of fluorescence seen in fractions 7–9 (Fig. 1b, d) after addition of Triton X-100 confirms the position of the liposome peak. The same panels indicate that there has been only a slight leakage of liposome contents—that is, the fluorescence not increased by detergent (fractions 15–17)—during the

**Table 2** Binding of fluoresceinated proteins or CF-containing protein-bearing liposomes to  $5 \times 10^6$  human peripheral blood leukocytes

| Fluorescent reagent           | pmol protein incubated | pmol CF or fluorescein |           |           |

| FTTC-goat F(ab') <sub>2</sub> |                        |                        |           |           |
| anti-mouse Ig (F-GaM)         | 110                    | 165                    | 7.7       | 0.2       |
| B1.1G6 liposomes              | 1.3                    | 103                    | ND        | 23*       |

Human peripheral blood leukocytes obtained by standard techniques were incubated in tissue culture medium containing 5% fetal calf serum, in the presence of 25  $\mu$ g ml<sup>–1</sup> B1.1G6 or without antibody. After washing, the cells were mixed with the indicated quantities of protein-bearing liposomes (from fraction 8 of Sepharose 4B column chromatography, Fig. 1), with FPA (Pharmacia) or with F-GaM (Cappel). All incubations were at 4 °C in the presence of 0.02% Na<sub>2</sub>S<sub>2</sub>O<sub>3</sub>. After washing, the cell pellets were lysed with 0.5% Triton and the supernatant measured for fluorescence. The fluorescence of fluoresceinated proteins is corrected for quenching, which is not relieved by Triton. The degree of quenching was determined by the difference between the fluorescence observed and that expected (excitation, 488 nm; emission, 520 nm) for the fluoresceinated proteins for the quantity of fluorescein found to be present by absorption ( $A_{488}$ ), with respect to an unquenched standard. Fluorescein in FPA is 78% quenched and in F-GaM is 44% quenched. The CF in liposomes could be measured directly by fluorescence after relief of quenching by addition of Triton; it was 84–86% quenched in intact liposomes. The quantities of fluorescein or CF incubated and bound were determined by comparison with a known concentration of CF, which has the same fluorescence quantum efficiency as fluorescein. ND, not determined.

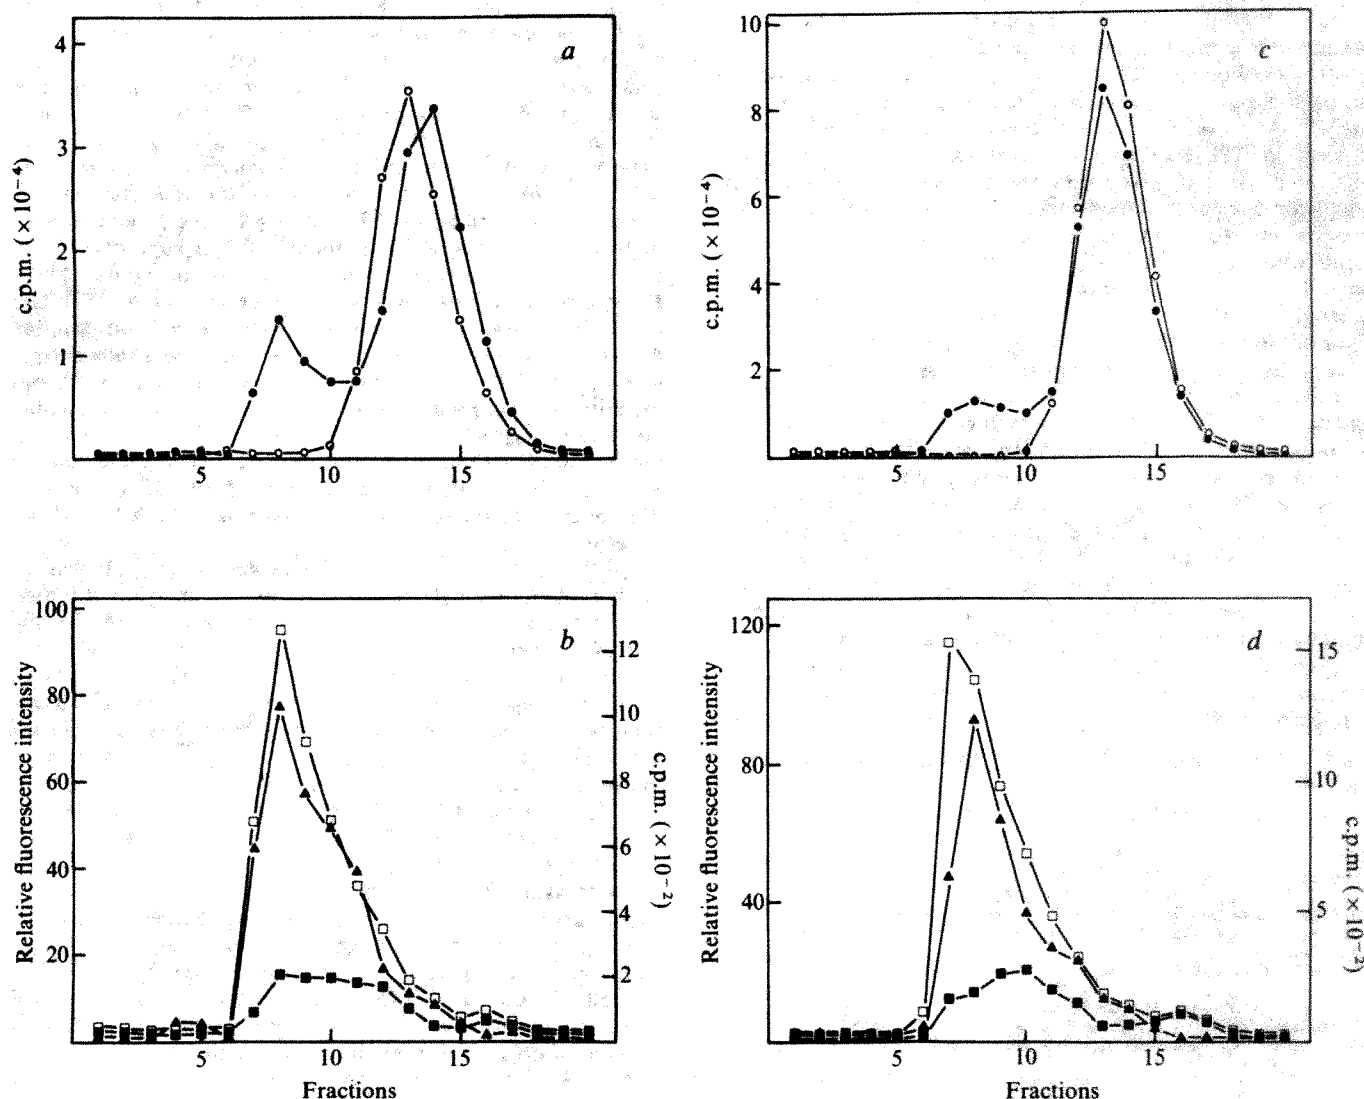

\* Liposomes incubated with  $5 \times 10^6$  mouse spleen cells bound 2.8 pmol CF.

reaction. We have not observed  $^{125}\text{I}$ -labelled protein in the void volume when we chromatographed liposomes and proteins containing DTP groups but not activated by reduction (our unpublished data).

Table 1 shows the results of a representative experiment demonstrating that the protein excluded in the void volume is, in fact, coupled to the surface of the liposomes. This experiment takes advantage of the fact that cells of *S. aureus*, strain Cowan I (SaCI), which express protein A on their surface, will bind to and precipitate certain classes of antibody<sup>9</sup>, including the B1.1G6 class. The result demonstrates that the binding of B1.1G6 antibody to liposomes does not impair recognition of the Fc region of the antibody by the SaCI. Liposomes bearing the covalently bound soluble homologous protein A were not precipitated by the SaCI. The co-precipitation of CF with  $^{125}\text{I}$ -

labelled B1.1G6 indicated that at least 60% of liposomes bear on their surface antibody molecules whose affinity for SaCI is unimpaired.

Liposomal B1.1G6 is also functional with respect to its antibody-combining site (Table 2). B1.1G6-bearing liposomes became bound to human cells, but not to mouse cells. Human cells preincubated with the B1.1G6 antibody and then washed, bound protein A-bearing liposomes; few liposomes were bound if cells were not incubated with the antibody. In experiments not presented here mouse cells preincubated with the monoclonal anti-I-A<sup>k</sup> antibody 10-2-16 (ref. 10) also bound protein A liposomes. The use of protein A on liposomes would thus permit aliquots of a single liposome preparation to be directed at multiple targets, limited only by the availability of antibodies of the appropriate specificity and class.

**Fig. 1** Column chromatography and preparation of protein-bearing liposomes. Protein bound to liposomes or proteins alone were fractionated as follows. The liposome-protein reaction mixture (400  $\mu\text{l}$ ) or 200  $\mu\text{l}$  of  $^{125}\text{I}$ -labelled reduced proteins were applied to a  $1.5 \times 5$  cm column of Sepharose 4B run at  $7.2 \text{ ml h}^{-1}$ ; fractions are 0.6 ml. Aliquots were measured for  $^{125}\text{I}$ ,  $^{14}\text{C}$  and also for CF fluorescence. Fluorescence measurements were made with a Farrand Mark I spectrofluorometer (excitation 488 nm; emission 520 nm) before and after releasing entrapped CF with 0.5% Triton X-100. An unquenched fluorescence standard (66 nM CF) was set at unity for the scale. *a, b*, B1.1G6 and liposomes; *c, d*, protein A and liposomes. The liposome-protein coupling reaction was performed as follows. Dipalmitoyl phosphatidylethanolamine (DPPE, Calbiochem), 10  $\mu\text{mol}$ , was mixed in chloroform/methanol 9:1 (C:M) with  $^{14}\text{C}$ -PE (NEN) to a final specific activity of  $0.15 \mu\text{Ci } \mu\text{mol}^{-1}$ . To 10  $\mu\text{mol}$  was added 12  $\mu\text{mol}$  SPDP and 20  $\mu\text{mol}$  triethylamine. After 2 h at  $25^\circ\text{C}$  the organic phase was extracted with water, dried and the product redissolved in C:M to a final concentration of  $5 \mu\text{mol ml}^{-1}$ . TLC on silical gel revealed a single spot with  $R_f$  0.47 (50  $\mu\text{g}$  sample in  $\text{CHCl}_3/\text{MeOH}/\text{H}_2\text{O}$  65:25:4). The yield (DPPE-DTP) was 90%, based on  $^{14}\text{C}$ . For the formation of liposomes: to 10  $\mu\text{mol}$  dipalmitoyl phosphatidylcholine (DPPC, Sigma) was added 5  $\mu\text{mol}$  cholesterol (Applied Science Labs) and 0.6  $\mu\text{mol}$   $^{14}\text{C}$ -DPPE-DTP, all in C:M. Solvent was evaporated and liposomes formed by sonication under  $\text{N}_2$  for 40 min at  $45^\circ\text{C}$  in the presence of 3 ml 40 mM CF in 0.01 M HEPES-buffered saline, pH 7.45. Unencapsulated CF was removed by gel filtration.  $^{125}\text{I}$ -labelled or unlabelled proteins,  $2.4 \text{ mg ml}^{-1}$ , were incubated with 0.08 mM (for B1.1G6) or 0.5 mM (for protein A) SPDP at pH 7.45 for 30 min at  $25^\circ\text{C}$ . Unreacted SPDP was removed by gel filtration and protein-bound DTP was reduced with 50 mM dithiothreitol in 0.1 M acetate-buffered saline, pH 4.5, for 20 min. Liposomes (500  $\mu\text{l}$ ), at a concentration of 2 mM (in DPPC), were incubated overnight at  $25^\circ\text{C}$  with an equal volume of  $^{125}\text{I}$ -labelled or unlabelled reduced protein,  $1 \text{ mg ml}^{-1}$ , pH 7.45. Samples for  $^{14}\text{C}$  counting were incubated with unlabelled protein.  $\bullet$ ,  $^{125}\text{I}$ -labelled protein incubated with liposomes (*a, c*);  $\circ$ ,  $^{125}\text{I}$ -labelled protein alone (*a, c*);  $\blacktriangle$ ,  $^{14}\text{C}$ -PE in liposomes (*b, d*);  $\blacksquare$ , CF fluorescence before, and  $\square$ , after, addition of Triton (*b, d*).

Table 2 indicates another feature of liposome encapsulation, namely, the large quantity of material that can be carried. The fluorescein/protein (F/P) ratio of directly fluoresceinated antibody (using fluorescein isothiocyanate (FITC)) is limited by denaturation of the antibody to usually not more than 3 or 4 (ref. 11). (Protein A can have a somewhat higher F/P ratio without denaturation.) In this experiment, the F/P ratio for antibody-bearing liposomes is 50 times greater than that of the directly fluoresceinated antibody, and need only be limited by the solubility of the encapsulated material, which for CF is at least sixfold higher than that used here.

Because the coupling conditions minimize homopolymerization of proteins or liposomes, this technique avoids the aggregation and denaturation of IgG observed in techniques associating antibody and liposomes noncovalently, by sonication<sup>12,13</sup>. We have introduced approximately two DTP groups per antibody molecule. In these conditions the titre of the protein is only minimally reduced in a sensitive radioimmunoassay (manuscript in preparation).

We have been unable to associate protein A with liposomes using the glutaraldehyde technique described by Torchilin *et al.*<sup>14,15</sup>. Also, a technique has recently been reported<sup>16</sup> for the formation of PE-derivatives of proteins by reacting them with an activated PE-derivative, following exposure of their intrinsic sulphhydryl residues. The protein-PE complex is then used for passive sensitization of liposomes. This method could not be used with protein A, as it lacks cysteine<sup>17</sup>. In addition, by analogy with 'active' against 'passive' incorporation of dinitrophenyl-PE into liposomes<sup>18</sup>, the inclusion of a prosthetic group into liposomes at the time they are formed, as in the present case, is likely to be a more efficient process.

In experiments to be presented elsewhere, we have encapsulated methotrexate in liposomes to which we have covalently coupled antibody and protein A. In this context we are extending our studies on immunological targeting of methotrexate in liposomes<sup>19,20</sup>. We have also used SPDP to couple albumin, avidin and affinity-purified rabbit antibody to liposomes, and the technique can, in principle, be applied to any compound containing an available amino group. Thus, encapsulation and specific targeting of numerous water-soluble compounds of biological and chemotherapeutic interest is quite feasible.

Pierre Henkart suggested the use of SaCl to precipitate antibody-bearing liposomes. This research was supported by funds from INSERM, CNRS and DRGST (ACC FK, 1980).

**Note added in proof:** A detergent dialysis technique for the association of monoclonal antibodies with liposomes has recently been reported<sup>21</sup>.

## Cell cycle kinetics in human lymphocyte cultures

Kanehisa Morimoto\* & Sheldon Wolff

Laboratory of Radiobiology and Department of Anatomy, University of California, San Francisco, San Francisco, California 94143

Short-term cultures of phytohaemagglutinin (PHA)-stimulated human lymphocytes are widely used to detect chromosome-damaging agents<sup>1,2</sup>, possible human exposure to mutagenic carcinogens<sup>1,2</sup> and the immune response of blood<sup>3</sup>. Because the results are affected by the number of cell divisions before sampling<sup>1,2,4,5</sup>, an accurate knowledge of lymphocyte proliferation in culture is essential for these studies. Unfortunately, the information available on the lymphocyte proliferative characteristics is quite conflicting. For instance, although after stimulation of blood lymphocytes with PHA the cultures soon contain cells that have divided different numbers of times<sup>6,7</sup>; this heterogeneity has been explained variously as a difference in cell-cycle times<sup>8,9</sup> or in the times when the cells start blastogenesis by responding to PHA<sup>10-12</sup>. Prolonged treatment with high concentrations of <sup>3</sup>H-thymidine (TdR) have often been used to investigate lymphocyte proliferation<sup>8,10,13,14</sup>. Incorporated <sup>3</sup>H-TdR can, however, affect cell kinetics<sup>15-19</sup>. The differential staining of sister chromatids<sup>20</sup> in cells dividing for different numbers of times in the presence of bromodeoxyuridine (BUdR) can be used to study cell kinetics<sup>7,8,12</sup>. In experiments combining sister chromatid differential staining and autoradiography, we show here that <sup>3</sup>H-TdR labelling at more than 0.1  $\mu\text{Ci ml}^{-1}$  slows lymphocyte cycling, and that the heterogeneity of different generations of cells is caused by a difference in the times when they start their first DNA synthesis in response to PHA.

PHA-stimulated human lymphocytes were cultured in medium containing BUdR so that cells dividing for the first, second and third time after initiation of culture could be distinguished by the differential staining pattern of sister chromatids in slides stained with fluorescence-plus-Giemsa (FPG)<sup>20</sup>. When metaphase cells from cultures were examined at various times after initiation, it was found that the relative numbers of 1st, 2nd and 3rd or subsequent generation cells shift with increasing culture times (data not shown, see ref. 7). We have already shown that cell division delay induced by chemical treatments is clearly manifested as shifts in the relative proportion of these metaphases<sup>7</sup>.

To measure the effect of <sup>3</sup>H-TdR on cell proliferation, a simple combination method of sister chromatid differential staining and autoradiography was developed (Fig. 1). Cultures were established with 20  $\mu\text{M}$  BUdR and exposed from the 32nd to the 40th hour to <sup>3</sup>H-TdR (specific activity, 52 Ci mmol<sup>-1</sup>) at concentrations of 0.05-5  $\mu\text{Ci ml}^{-1}$ . Consequently, at the highest concentration used the medium contained only 0.1  $\mu\text{M}$  thymidine. An 8-h treatment was selected, because treatments for 4-24 h are commonly used for labelling human lymphocytes in culture. The cultures were then fixed at 64 h and the numbers of cells dividing for the first, second or third time determined in FPG-stained slides<sup>7,12</sup>.

At concentrations above 0.2  $\mu\text{Ci ml}^{-1}$ , <sup>3</sup>H-TdR affects the distribution of each generation metaphase cells in a clear dose-dependent manner (Fig. 2a). In 64-h cultures exposed to  $\leq 0.2 \mu\text{Ci ml}^{-1}$  <sup>3</sup>H-TdR, approximately 10% of the metaphases were in their first division, 40% in their second division and 50% in their third. In cultures exposed to more than 0.2  $\mu\text{Ci ml}^{-1}$  <sup>3</sup>H-TdR, the proportion of 1st-generation metaphases increased, whereas that of 3rd-generation metaphases

Labelling was with  $0.1 \mu\text{Ci ml}^{-1}$   $^3\text{H}$ -TdR. I or II represents the metaphases whose labelling pattern indicates the  $^3\text{H}$ -TdR incorporation in the first or second cell cycle, respectively (for details see Fig. 1 legend). The criteria for labelling and the abbreviations used were the same as those in Fig. 2. For metaphases whose labelling pattern indicated  $^3\text{H}$ -TdR incorporation in the second S phase (Fig. 1), if more than one-third (or two-thirds) of the chromosomes were labelled on both chromatids (for 2nd-generation metaphases) or on lightly stained chromatids (for 3rd-generation metaphases), they were designated as labelled (or heavily labelled).

decreased. The percentage of 2nd-generation metaphases exhibited a small peak at  $0.5 \mu\text{Ci ml}^{-1}$  and then at higher concentrations decreased more markedly than did the 3rd-generation metaphases, apparently indicating that the induced mitotic delay in 2nd-generation cells might be longer than that in 3rd-generation cells.

**Fig. 1** Schematic presentation of the simple combination method of  $^3\text{H}$ -TdR labelling and sister chromatid differential staining. When cells are incubated continuously with BUdR and pulse-labelled with  $^3\text{H}$ -TdR at different times after initiation of culture, metaphase cells from resultant cultures have various combinations of the differential staining pattern of sister chromatids and the distribution of autoradiographic silver grains over the chromosomes. The differential staining pattern of sister chromatids yields information on how many times a cell has divided in culture, and the distribution of autoradiographic grains over the chromosomes indicates when the cell synthesized DNA. 1st-Division cells contain chromosomes with both sister chromatids stained uniformly darkly. 2nd-Division cells contain only harlequin chromosomes with one chromatid darkly stained and its sister chromatid lightly stained, whereas 3rd-division cells contain some harlequin chromosomes and other chromosomes with both sister chromatids stained uniformly lightly. For cells which have incorporated  $^3\text{H}$ -TdR in their first S phase, a 1st-division cell has labelling on both chromatids of a chromosome whereas a 2nd-division cell is labelled only on lightly stained chromatids. A 3rd-division cell has labelling on lightly stained chromatids only where both chromatids of a chromosome are lightly stained. For cells which have incorporated  $^3\text{H}$ -TdR in their second S phase, a 1st-division cell has no labelling at all, a 2nd-division cell has labelling on both chromatids and a 3rd-division cell is labelled on lightly stained chromatids where both chromatids of a chromosome are lightly stained as well as where one is lightly stained and one is darkly stained. Such combination patterns of labelling and sister chromatid differential staining are the same in whichever division cycle sister chromatid exchanges take place, although here only those which occurred in the 2nd cell cycle are shown for clarity.

Autoradiograms of the same slides showed that the shift in the relative proportions was more pronounced among labelled metaphases (Fig. 2b), being much more marked in heavily labelled metaphases (Fig. 2c). 'Unlabelled' metaphases, categorized as those other than the labelled cells, showed a small shift in the relative proportions when exposed to more than  $1 \mu\text{Ci ml}^{-1}$   $^3\text{H}$ -TdR (data not shown). The data also indicated that, with exposure to  $^3\text{H}$ -TdR between 32 and 40 h of culture, many more 2nd- than 3rd-generation cells had been labelled in their first S phase (Fig. 2b, c) and that the apparently longer mitotic delay in 2nd-generation metaphase cells (Fig. 2a) was only a reflection of such differential labelling. Labelled 1st-generation metaphases were found only in the cultures exposed to more than  $0.1 \mu\text{Ci ml}^{-1}$   $^3\text{H}$ -TdR. Corresponding decreases in both the mitotic indices and the percentage of transformed cells (Fig. 2d) also occurred. These data indicate that  $^3\text{H}$ -TdR labelling with concentrations above  $0.1 \mu\text{Ci ml}^{-1}$  slows lymphocyte proliferation in culture.

In preliminary experiments we have noted that cell division kinetics are not perturbed by washing the cells and replacing the medium, by treatment with as high as  $10 \mu\text{M}$  cold thymidine, or by the use of BUdR at concentrations up to  $40 \mu\text{M}$  (data not shown). We thus believe that the observed mitotic delay is due to incorporated  $^3\text{H}$ -TdR.

Autoradiograms of FPG-stained cells labelled with  $0.1 \mu\text{Ci ml}^{-1}$   $^3\text{H}$ -TdR at different times after initiation of culture have also shown (Table 1) that the majority of 2nd-generation metaphases seen in a 64-h culture started DNA synthesis at 32-40 h after initiation, and that none of the 1st-generation metaphases started DNA synthesis before 40 h, a quarter of them entering their first S phase at 40-48 h. Most of the 3rd-generation metaphases entered their first S phase at 24-32 h and their second S phase at 40-48 h. These data thus indicate that in cultures, the older-generation cells begin their first DNA synthesis at earlier times after the start of incubation. As shown in Fig. 2, treatment with higher concentrations of  $^3\text{H}$ -TdR perturbs cell division kinetics such that cells with more incorporated  $^3\text{H}$ -TdR have longer cell-cycle times.

Crossen and Morgan<sup>8</sup> have recently found that the small proportion of 1st-division metaphases seen in 72-h cultures treated with  $2 \mu\text{Ci ml}^{-1}$   $^3\text{H}$ -TdR entered S phase before the 34th hour of incubation. We think that this observation of extraordinarily long cell-cycle times is the result of prolonged  $G_2$  phases caused by the radiation from incorporated  $^3\text{H}$ -TdR.

Pollack *et al.*<sup>19</sup> also showed by flow cytometric (FCM) analysis that an 18-h treatment with  $0.5 \mu\text{Ci ml}^{-1}$   $^3\text{H}$ -TdR increased the relative proportion of lymphocytes in the  $G_2$  plus M phase, suggesting an inhibition of cell proliferation. Such a  $G_2$  block, measured by FCM analysis, was also reported in several mammalian cell lines treated with low concentrations of  $^3\text{H}$ -TdR<sup>17,18</sup>. However, the elevation in the  $G_2$ +M peak does not always indicate an actual delay in cell proliferation because the FCM analysis provides only a static representation of the distribution of cells about the cell-cycle phases<sup>17-19</sup> and because a transient

**Fig. 2**  $^3\text{H}$ -TdR-induced changes in the relative proportion of metaphase cells in the 1st (X<sub>1</sub>, triangles), 2nd (X<sub>2</sub>, circles) or 3rd (X<sub>3</sub>, squares) division in 64-h cultures. Changes in the proportion among (a) total, (b) labelled (l.), or (c) heavily labelled (h.l.) metaphases are shown, as are (d) changes in the mitotic indices and the percentage of transformed cells. Two healthy human males aged 30 yr (open symbols) and 33 yr (half-closed symbols) were used as blood donors. Cells were treated with  $^3\text{H}$ -TdR at the appropriate concentration from the 32nd to the 40th hour after initiation of cultures. The treatment with  $^3\text{H}$ -TdR was terminated by washing the cells three times and resuspending them in prewarmed complete medium. A 64-h incubation time was selected because preliminary experiments indicated that the cultures would contain relative proportions of 1st-, 2nd- and 3rd-division metaphases appropriate for the observation of induced perturbations in cell division kinetics. In FPG-stained preparations, cells dividing for the first, second or third time in culture were determined by the differential staining pattern of sister chromatids (Fig. 1). This experiment was repeated with blood from the same donor (left-half-closed symbols). For autoradiography of FPG-stained cells, slides were dipped in a 1% Formvar solution<sup>23</sup> to prevent the formation of chemical grains by direct contact between the autoradiographic nuclear emulsion and the Giemsa stain. The slides were then dipped in Ilford L-4 emulsion and developed after 1–90 days exposure at 4°C. The exposure time was inversely proportional to the  $^3\text{H}$ -TdR concentrations. The degree of labelling was determined by the number of chromosomes labelled in a cell. A 1st-division metaphase was designated as labelled if more than one-third of the chromosomes were labelled on both chromatids; if more than two-thirds of the chromosomes were so labelled the cell was considered to be heavily labelled. Similarly, a second division cell was considered labelled (or heavily labelled) if more than one-third (or two-thirds) of the chromosomes were labelled on the light chromatid. 3rd-Division cells were considered labelled (or heavily labelled) if labelling occurred in the lightly stained chromatids of more than one-sixth (or one-third) of those chromosomes with both chromatids lightly stained in the centromeric regions. These criteria were applied for labelled metaphase cells that incorporated  $^3\text{H}$ -TdR in their first S phase after initiation. Metaphase cells whose labelling pattern indicated  $^3\text{H}$ -TdR incorporation in the second S appeared more frequently in cultures treated at the higher concentrations of  $^3\text{H}$ -TdR. These cells can also be used to indicate cell division delay (data not shown). From each culture 200 metaphases were scored for the distribution of 1st-, 2nd- and 3rd-division cells, and 100 metaphases from each culture were analysed for the distribution of labelled metaphases. Mitotic indices and the percentage of transformed cells were based on 2,000 cells.

a dose-dependent change in the distribution of 1st-, 2nd- and 3rd-division cells in  $^3\text{H}$ -TdR-treated and control cultures<sup>7</sup>.

The present study has thus shown the simple combination of autoradiography and differential staining of sister chromatids to be a sensitive method for detecting mitotic delay in human lymphocyte cultures. It can be easily applied to other cell cultures to check the effect of  $^3\text{H}$ -TdR labelling on cell proliferation. Our data suggest that some information available on human lymphocyte proliferation might be misleading because they were often obtained with lengthy  $^3\text{H}$ -TdR labelling at high concentrations, which induce mitotic delay. We have also presented direct evidence that the heterogeneity with respect to different generation metaphases seen in a culture is a reflection of a difference in the times the cells enter their first DNA-synthesis period, and that the cells have about the same generation times thereafter.

This work was performed under the auspices of the US Department of Energy. K.M. is a Fellow of the Japan Society for the Promotion of Science.

increase of cells in the G<sub>2</sub> + M can be observed with an unaltered population doubling time of cultured cells<sup>17,18</sup>. Here we have shown directly that an 8-h treatment with as low as 0.2  $\mu\text{Ci ml}^{-1}$   $^3\text{H}$ -TdR delays lymphocyte proliferation in culture.

Purrott *et al.*<sup>21</sup> showed by FPG-differential staining of PHA-stimulated lymphocytes that X-ray irradiation of G<sub>0</sub> cells induces a mitotic delay of 1 h Gy<sup>-1</sup>. In the present experiments accurate estimations of the dose from incorporated  $^3\text{H}$ -TdR and of the amount of delay are not possible because of the complications of both the uptake of  $^3\text{H}$ -TdR and the rate of cell division. Assuming a dose of approximately 5 mGy per disintegration<sup>22</sup>, however, the dose rate received by labelled cells in the first cell cycle after a treatment of 0.5  $\mu\text{Ci ml}^{-1}$   $^3\text{H}$ -TdR can be estimated to be roughly 30 mGy h<sup>-1</sup>. The mitotic delay observed with this treatment is 4–6 h, which was estimated from

## Effects of an Earth-strength magnetic field on electrical activity of pineal cells

P. Semm, T. Schnelder & L. Vollrath

University of Mainz, Department of Anatomy, Neurophysiology Laboratory, 6500 Mainz, Saarstr. 19/21, FRG

Although magnetic fields can influence biological systems, including those of man and other vertebrates<sup>1-4</sup>, no central nervous structure has been identified that might be involved in their detection. From a theoretical point of view, the pineal organ might be such a structure for the following reasons: (1) It is involved in the regulation of circadian rhythms<sup>5</sup> and is thus essential for migratory restlessness ('Zugunruhe')<sup>7</sup>. Orientation at that time can be altered by an artificial magnetic field (MF) with a direction differing by 90° from that of the Earth. Circadian rhythms can be inhibited from phase shifting by compensation of the Earth's MF and can be influenced by an artificial MF<sup>6</sup>. (2) The pineal organ is strongly dependent on its sympathetic innervation<sup>8</sup> and the sympatho-adrenergic system as a whole is sensitive to magnetic stimuli<sup>9</sup>. (3) The pineal organ is a light-sensitive time-keeping organ<sup>10,11</sup> and could form part of a combined compass-solar-clock system, which has been postulated for maintaining orientation in birds<sup>12</sup>. We have therefore investigated the effect of a MF on electrophysiological activity of the guinea pig pineal organ, which is a useful system for such studies on individual cells<sup>11,13</sup>. We report here that activity was depressed by an induced MF and restored when the MF was inverted.

We abandoned attempts to use a small permanent magnet, as the MF produced was neither homogeneous nor accurately measurable in the area of the pineal organ. We used 16 male guinea pigs (300–900 g), anaesthetized with urethane. In each experiment a tracheotomy was performed, and the animal artificially respired and mounted in a stereotaxic frame. Body temperature was maintained using a heating pad and the electrocardiogram continuously monitored. The dorsal surface of the brain was exposed, and a single micropipette inserted into the posterior part of the pineal organ, just under the confluence of the sagittal and transverse sinus. Extracellular activity was

recorded through the micropipette, filled with 4 M NaCl solution saturated with fast green for verifying recording sites histologically. The MF was generated by two Helmholtz coils (radius 3.6 cm), one under the jaw and the other on top of the head, with 3.6 cm distance between them. The strength of the MF in the middle of the two coils was

$$B_H = \left(\frac{4}{5}\right)^{\frac{1}{2}} \cdot \frac{\mu_0 \cdot n \cdot I}{R}$$

where  $B_H$  is the magnetic field strength,  $\mu_0$  the permeability of free space,  $R$  the radius (3.6 cm),  $n$  the winding number (150) and  $I$  the intensity of current (for example:  $I_1$  for 0.3 Oe = 8.0073 mA and  $I_2$  for 0.8 Oe = 21.3528 mA). The MF thus calculated was measured by a Hall-sound and was shown to be relatively homogeneous around the animal's head. The direction of the current and thereby the polarity of the MF could be altered. The artificial MF was added to the vertical component of the Earth's MF when the top coil was made the south pole. It compensated, or inverted, the vertical component when the top coil was made the north pole. The activity maintained by the cells under study was averaged by an averager system with a time base of 1 s per bin (total bin number = 256; a bin is the period of time during which the incoming electrical potentials are summed). The spike number of each averager histogram was determined by an electric counter. The histograms were read and plotted on a recorder every 4 min 16 s.

Before the MF stimulus was applied, we checked that short-term optic and acoustic stimuli had no effect on the pineal cells and that the maintained activity of a given cell was relatively constant (measured for about 16 min, Fig. 1b, c). Then the first MF stimulus of 0.5 Oe was applied for 17 min 4 s and, after 8 min, a second stimulus of the same strength for 8 min. Of a total of 71 cells tested in 16 male guinea pigs, 56 did not respond (Fig. 1a). A cell was classified as sensitive to stimulation only when spontaneous electrical activity was depressed by more than 30%. Fifteen cells (from 11 animals) showed a marked response to MF stimulation; as Fig. 1b and c show, maintained activity was diminished by more than 50%, well out of the range of spontaneous oscillations of pineal electrical activity. The first clear effect could be measured after a latency period of about 2 min, not visible in the figure due to averaging at 4 min 16 s intervals. When the MF was switched off, all cells retained a diminished activity, lasting as long as recording could be continued (up to 30 min in some cases). A second round of the same stimulus had no effect (Fig. 1b, c) even when the strength of the stimulus was varied (not shown).

Fig. 1 a, The number of spikes from four single pineal cells (counted every 4 min 16 s, averaging time) which could not be influenced by a magnetic stimulus of 0.5 Oe. b, Reaction of a pineal cell to a MF of 0.5 Oe. c, Another pineal cell, the maintained activity of which is diminished by a MF of 0.5 Oe. A second stimulus had no effect in either cell.

**Fig. 2** The spike number of three single pineal cells. Cell no. 1 shows a clear depression of activity after a magnetic stimulus of 0.5 Oe and remains depressed after cessation of the stimulus. After an inverted stimulus of 0.5 Oe, cell activity returns to output level and is depressed again by a stimulus of 0.10 Oe, south pole up. After a period of depression, activity increases again after a short stimulus of 0.5 Oe with inverted polarity of MF. Cell no. 2 shows a similar reaction, whereas cell no. 3 does not reach its output level after the first application of the inverted MF. After the second inverted magnetic stimulus, cell activity reached output level again.

When the polarity of the MF was changed in 3 of the 15 responsive cells, their activity immediately returned to the initial level (Fig. 2). With the exception of cell no. 3, they all reached this level after 8–12 min. The latency of the renewed activation was also in the range of 2 min (not shown). When the inverted MF was switched off the cells retained their normal activity, which could be depressed again by a low MF stimulus of 0.10 Oe, pointing to a relatively high sensitivity of the cells. After a further inversion of polarity, the cells were again activated. In one case maintained activity could be directly stimulated by an inverted MF (north pole up).

In other brain structures (inferior and superior colliculi, corpus callosum and epithalamus) in identical experimental conditions, no reactions to magnetic stimuli could be measured. Thus, the cellular response of cells to magnetic stimuli is not universal and the reactions measured were not due to magnetic or electrical interference with the recording system.

The role of the pineal organ has been clarified in only a few species. In photoperiodic mammals it influences the hypothalamo-pituitary-gonadal axis and controls the atrophy of the gonads during winter by an increased output of the hormone melatonin<sup>14</sup>. In birds the pineal is involved in the regulation of locomotor activity<sup>15</sup>. In various species the pineal organ is readily influenced by external (light, noise, ambient temperature, olfactory stimuli) and internal (sex steroids, noradrenaline) factors<sup>6</sup>. The heterogeneity of the pineal cells has been demonstrated in the guinea pig although individual functions remain to be elucidated. This may help to explain why not all cells we recorded clearly responded to MF stimuli.

As this is apparently the first report that the pineal responds to changes in an artificial MF, we can offer no corroborative evidence for our findings. Indirect evidence is that migratory restlessness and locomotor activity, which have been clearly shown to be affected by the pineal, can be influenced by artificial or natural MFs. We also feel it is significant that for orientation, in addition to sensing the Earth's MF, time-keeping ability is required<sup>12</sup>. As the pineal organ is a sort of time-keeping device<sup>10</sup>, it might be an ideal site for integration, particularly as birds do not simply switch between magnetic and Sun compasses<sup>12</sup>.

Whether or not the pineal organ itself senses changes of MF is not known. The organ is heavily innervated by sympathetic

fibres<sup>16</sup> and the sympathetic nervous system can be affected by magnetic stimuli, so that the effect may well be indirect. The lack of appreciable amounts of iron in the pineal organ<sup>17,18</sup> makes it unlikely that the magnetite (magnetic iron oxide) required for transducing magnetic stimuli in bacteria<sup>19</sup> is present.

Interestingly, it has been proposed<sup>20</sup> for migratory birds and homing pigeons that the MF is detected in the lateral eyes, although phylogenetically the pineal organ corresponds to the median eye of lower vertebrates<sup>6</sup>. The pineal organ of higher vertebrates is derived from the photoreceptive pineal organ of lower vertebrates<sup>21</sup> and is connected to the lateral eyes by the nucleus suprachiasmaticus and the sympathetic nervous system<sup>22</sup>.

We thank the Volkswagenwerk-Stiftung for financial support.

**Note added in proof:** Recent experiments carried out in our laboratory indicate that pineal cells of homing pigeons, which according to other authors use the natural magnetic field for orientation, also respond clearly to artificial magnetic fields.

## $\beta$ -Carboline-3-carboxylic acid ethyl ester antagonizes diazepam activity

S. S. Tenen & James D. Hirsch

Department of Biological Research, G. D. Searle & Company,  
PO Box 5110, Chicago, Illinois 60680

Analogous to the progression of events in the opiate receptor-enkephalin area, the first reports<sup>1-3</sup> that benzodiazepines have selective and specific high-affinity binding sites in brain have stimulated a search for the endogenous 'ligand' or substance that might normally act at these sites<sup>4-9</sup>. Braestrup and co-workers have extracted from human urine a  $\gamma$ -fraction (ref. 10) which they have recently<sup>11</sup> identified as  $\beta$ -carboline-3-carboxylic acid ethyl ester ( $\beta$ CEE). They reported that this substance is extremely potent in displacing <sup>3</sup>H-diazepam from brain binding sites and proposed that a  $\beta$ -carboline-3-carboxylic acid derivative might, in part, be the endogenous ligand for the brain benzodiazepine receptor. We have examined several synthetically derived  $\beta$ -carboline-3-carboxylic acid analogues and now present data obtained from testing only the  $\beta$ CEE described by Braestrup *et al.* In addition to confirming these workers' observation that this compound is a potent displacer of <sup>3</sup>H-diazepam from brain tissue, our pharmacological data indicate that  $\beta$ CEE has activity that is opposite to, rather than similar to, that of diazepam.

The *in vitro* <sup>3</sup>H-diazepam binding assay was carried out in triplicate according to the method of Mackerer *et al.*<sup>12</sup>, using whole rat brain membranes. <sup>3</sup>H-diazepam was present at 4.0 nM and nonspecific binding was determined in the presence of 4  $\mu$ M unlabelled diazepam. Our assay yielded an IC<sub>50</sub> for  $\beta$ CEE of 1.9  $\pm$  0.1 nM (mean  $\pm$  s.e., eight experiments) which closely corresponds to the reported results<sup>11</sup> and is in the range of the most potent benzodiazepines.

Diazepam has anticonvulsant activity and is especially potent in blocking pentylenetetrazole (PTZ)-induced clonic seizures in mice. We determined the PD<sub>50</sub> (50% protective dose) of diaze-

Table 2 The effect of either normal saline or  $\beta$ CEE on the CD<sub>50</sub> of PTZ

| Pretreatments<br>(mg per kg, i.v.) | PTZ<br>dose range<br>(mg per kg, i.v.) | No.<br>of mice | CD <sub>50</sub> of PTZ<br>(mg per kg) |
|------------------------------------|--|----------------|--|
| Normal saline                      | 20-35                                  | 48             | 26.0 (23.8-28.5)                       |
| $\beta$ CEE (3.2)                  | 5-20                                   | 48             | 14.3 (12.3-16.8)                       |
| $\beta$ CEE (10)                   | 5-20                                   | 48             | 12.3 (10.3-14.8)                       |
| $\beta$ CEE (32)                   | 1-15                                   | 48             | 8.3 (6.5-10.6)                         |

The subjects were male HAM/ICR CD-1 mice weighing 20-27 g at the time of the experiments. The CD<sub>50</sub> (convulsive dose for clonic seizures) of PTZ for each of the four experimental conditions was estimated from four dose levels using 12 mice per dose. The CD<sub>50</sub>s (and 95% confidence limits) were calculated by a Searle computer program based on the method of Litchfield and Wilcoxon<sup>13</sup>. The lowest and highest doses of PTZ administered to mice in each pretreatment group are also presented. In all four pretreatment groups none of the mice convulsed at the lowest dose of PTZ and 12 out of 12 mice convulsed at the highest dose.

pam against PTZ-induced clonic seizures in mice pretreated with either normal saline or  $\beta$ CEE at 3.2, 10 or 32 mg per kg. The experimental design was as follows: normal saline or  $\beta$ CEE was given intravenously (i.v.); 5 min later DZM was administered intraperitoneally (i.p.), followed after 20 min by i.v. administration of 35 mg per kg PTZ. Pretreatment with  $\beta$ CEE produced a clear and pronounced dose-responsive increase in the PD<sub>50</sub> of diazepam against PTZ-induced clonic convulsions (Table 1). This antagonism of the anticonvulsant effect of diazepam is best illustrated by examining the effects of  $\beta$ CEE on a single diazepam dose. For example, diazepam at 1 mg per kg (in the control group) blocked PTZ-induced convulsions in all 10 mice tested. However, when pretreated with only 3.2 mg per kg  $\beta$ CEE there was a complete reversal in that all 10 mice convulsed at this same dose of diazepam.

On the basis of these data, it is tempting to speculate that, analogous to the naloxone-opiate relationship, the  $\beta$ CEE antagonism of diazepam is primarily due to competitive receptor occupancy. However, it seems that a more complex relationship exists. We examined the direct effects of  $\beta$ CEE on the dose (CD<sub>50</sub>) of PTZ required to induce clonic convulsions. Mice received i.v. administrations of either normal saline or  $\beta$ CEE, 3.2, 10 or 32 mg per kg, and 25 min later various doses of PTZ were given i.v. As compared with controls,  $\beta$ CEE produced a dose-responsive decrease in the amount of PTZ required to induce clonic convulsions (Table 2). However,  $\beta$ CEE is not in itself a convulsant within the dose range we studied; i.v. doses of up to 75 mg per kg have failed to produce any overt signs of convulsions or tremors.

Thus,  $\beta$ CEE has an unusual pharmacological profile. It potentially displaces <sup>3</sup>H-diazepam from brain membranes, antagonizes the diazepam blockade of PTZ-induced convulsions, lowers the CD<sub>50</sub> of PTZ and has no convulsant activity of its own. This compound might constitute a new and unique class of pharmacological activity. In any case, it should be useful in learning more about the functions of the benzodiazepine receptor and its proposed endogenous ligand. It would be premature to infer that benzodiazepines are 'antagonists' rather than 'agonists' of the naturally occurring ligand, despite the pharmacology of  $\beta$ CEE, until the full identification of the endogenous ligand has been made. Even if the endogenous ligand should involve a  $\beta$ -carboline-3-carboxylic acid derivative we would therefore have tested only what might be a portion or analogue of this ligand. Again, borrowing from the opiate literature, we know that slight modifications of the structure of an agonist can result in markedly different pharmacological activity.

We acknowledge the technical assistance of A. Miller for the pharmacological studies, P. Sumner for the binding studies and P. Yonan for synthesizing  $\beta$ CEE.

Table 1 The effect of pretreatment with either normal saline or  $\beta$ CEE on the PD<sub>50</sub> of diazepam against PTZ-induced clonic convulsions

| Pretreatments<br>(mg per kg, i.v.) | Diazepam<br>dose range<br>(mg per kg, i.p.) | No.<br>of mice | PD <sub>50</sub> of diazepam<br>(mg per kg) |
|------------------------------------|---|----------------|---|
| Normal saline                      | 0.1-1.0                                     | 50             | 0.32 (0.23-0.43)                            |
| $\beta$ CEE (3.2)                  | 0.56-5.6                                    | 50             | 2.7 (2.1-3.5)                               |
| $\beta$ CEE (10)                   | 1.0-10                                      | 50             | 3.8 (2.8-5.2)                               |
| $\beta$ CEE (32)                   | 3.2-32                                      | 50             | 12.6 (9.7-16.3)                             |

The subjects were male HAM/ICR CD-1 mice (obtained from Charles River Breeders), weighing 20-27 g at the time of the experiments. The ED<sub>50</sub> of diazepam that blocked PTZ-induced clonic convulsions is here referred to as the PD<sub>50</sub> of diazepam. The diazepam PD<sub>50</sub> for each of the four pretreatment conditions was derived from five doses of diazepam (covering 1 log dose range in quarter-log steps) with 10 mice per dose. The PD<sub>50</sub>s (and 95% confidence limits) were calculated by a Searle computer program which is based on the method of Litchfield and Wilcoxon<sup>13</sup>. The lowest and highest doses of diazepam administered to the mice in each pretreatment group are also presented. In all four pretreatment groups 10 out of 10 mice convulsed at the lowest diazepam dose and none convulsed at the highest dose. Note that  $\beta$ CEE cannot be dissolved in water; therefore, this compound was administered as a 'suspension' in normal saline with a few drops of PG/Tween-80. All drug concentrations were adjusted so that the mice received 10 ml of this preparation per kg of body weight. Control animals received equal volumes of the saline PG/Tween-80 vehicle. The dorsal tail veins of the mouse were used for all i.v. administrations. Early pilot studies indicated that even the high dose of 32 mg per kg  $\beta$ CEE when administered i.p. failed to show the pharmacological effects reported here.

## Most of the coding region of rat ACTH $\beta$ -LPH precursor gene lacks intervening sequences

Jacques Drouin & Howard M. Goodman

Howard Hughes Medical Institute Laboratory, Department of Biochemistry and Biophysics, University of California, San Francisco, California 94143

The peptide hormones ACTH,  $\beta$ -endorphin,  $\alpha$ - and  $\beta$ -melanotropin (MSH) and possibly  $\gamma$ -MSH are synthesized in the pituitary gland by the processing of a 32,000-molecular weight (MW) polypeptide called proopiomelanocortin (POMC)<sup>1-5</sup>. The existence of a further precursor (pre form) to POMC containing an additional N-terminal 'leader' peptide has been suggested by analysis of the *in vitro* translation products of poly(A)-containing RNA from AtT-20 cells, a mouse ACTH-producing cell line of pituitary origin<sup>6</sup>. Nakanishi *et al.*<sup>7</sup> cloned and sequenced a cDNA copy of the bovine prePOMC mRNA. This sequence confirmed the known structure of the carboxyl half of POMC and revealed the presence of a new MSH-like moiety,  $\gamma$ -MSH, within the 16,000-MW amino half of the precursor (16K fragment). Recent experiments have suggested that this peptide may act in synergy with ACTH to increase corticosterone and aldosterone production *in vivo* and *in vitro*<sup>8,9</sup>. We have now isolated from a rat genomic DNA library<sup>10</sup> a segment of a DNA encoding most of POMC, using as probe a mouse 144-base pair cloned cDNA fragment encoding  $\beta$ -MSH and  $\beta$ -endorphin<sup>11</sup>. The cloned rat gene is one of two (or more) closely related POMC genes. The DNA sequence obtained shows that the cloned POMC gene is not interrupted by any intervening sequence (IVS) between the codon for amino acid 19 and the presumptive poly(A) addition site. This region of POMC encodes all the biologically active peptides mentioned above. The DNA sequence encoding the putative  $\gamma$ -MSH and the coding sequence that precedes it are highly conserved between rat and cow. This may indicate an as yet unrecognized biological function(s) for the NH<sub>2</sub>-terminal portion of the 16K fragment.

Polyadenylated RNA from the ACTH-secreting mouse cell line AtT-20 was previously used in this laboratory to clone a 144-base pair cDNA fragment encoding most of the  $\beta$ -MSH and  $\beta$ -endorphin sequences<sup>11</sup>. This mouse cDNA fragment has now been used as a probe to screen<sup>12</sup> a rat genomic DNA library<sup>10</sup> and isolate a fragment of rat DNA encoding POMC. A restriction enzyme cleavage map of the cloned rat DNA fragment was deduced by analysis of the products of double restriction endonuclease digestion and by hybridization of the DNA digests to the cloned mouse cDNA fragment or to single-stranded cDNA synthesized from poly(A)-containing AtT-20 RNA (Fig. 1). A *Xho*I + *Hind*III fragment (1.6 kilobases) contains all the

**Fig. 1** Restriction enzyme cleavage map of the cloned rat POMC gene. A rat genomic DNA library was constructed by cloning, in the bacteriophage  $\lambda$  vector Charon 4A (ref. 35), fragments of rat (Long-Evans) DNA produced by partial digestion with the restriction enzymes *Hae*III and *Alu*I<sup>10</sup>. This library was screened by filter hybridization<sup>12</sup> with the nick-translated<sup>13</sup> 144-base pair mouse cDNA fragment<sup>11</sup> and two clones showing positive hybridization were obtained. Restriction mapping analysis showed that the two clones are similar (not shown) and one of them, containing a 12-kilobase insert, was chosen for further work. *a*, The restriction enzyme cleavage map was deduced by analysis of the products of double restriction endonuclease digestion and by hybridization of the digests to the cloned mouse cDNA fragment. This 144-base pair fragment encodes the  $\beta$ -MSH and  $\beta$ -endorphin sequences. DNA (0.5  $\mu$ g) was digested with the indicated restriction enzymes and separated by electrophoresis on an 0.8% agarose gel. The gel was stained with ethidium bromide and photographed under short-wave UV light (left panel). The DNA was transferred to nitrocellulose paper<sup>13</sup> and hybridization was performed as described previously<sup>14</sup> except that 5  $\times$  SSC (1  $\times$  SSC is 0.15 M sodium chloride, 15 mM trisodium citrate) was used in the hybridization solution and 1  $\times$  SSC in the washes (right panel). A probe was prepared by nick translation<sup>15</sup> of the 144-base pair mouse AtT-20 cloned cDNA fragment. DNA size markers<sup>36</sup> are provided by a *Hind*III (*H3*) digest of wild type  $\lambda$  DNA (left lane). The probe hybridizes only to 3.8-kilobase *Hind*III (*H3*) and 6.7-kilobase *Xba*I (*Xba*) fragments and to a 2.6-kilobase fragment produced by double digestion with *Hind*III + *Xba*I (*H3/Xba*). This 2.6 kilobase fragment was later used for sequencing. *b*, Schematic representation of the restriction endonuclease cleavage map obtained for the cloned rat POMC gene. The solid lines represent the restriction map obtained for the cloned rat DNA and the dotted line the Charon 4A vector DNA. The following symbols are used to indicate the sites of restriction endonuclease cleavage: *Hind*III ( $\uparrow$ ), *Eco*RI ( $\downarrow$ ), *Xba*I ( $\diamond$ ), *Xho*I (*Y*), *Hpa*I (*Hinc*II) ( $\odot$ ), *Bam*HI ( $\square$ ), *Pst*I ( $\bullet$ ), *Acl*I ( $\times$ ) and *Hae*III ( $\blacksquare$ ). All the POMC coding sequences contained in this cloned segment of rat DNA are within the single *Xho*I site (*Y*) and the *Hind*III site ( $\uparrow$ ) at the far right of the middle line of the figure.

cloned rat sequences that are complementary to the mouse cDNA fragment but a larger (2.6 kilobase) *Xba*I + *Hind*III fragment was later used for sequencing.

The restriction map of the cloned rat POMC gene can be compared with POMC sequences present in rat genomic DNA by the filter hybridization method of Southern<sup>13</sup>. Rat HTC cell DNA was digested with various restriction enzymes, transferred to nitrocellulose filters<sup>13</sup> and hybridized<sup>14</sup> to the nick-translated<sup>15</sup> mouse cDNA fragment. Most digests show hybridization of unequal intensity to two bands (Fig. 2); however, a consistent restriction map can be independently derived for the strong and weak hybridizing bands. The sizes of the weakly hybridizing fragments correspond exactly to fragments present in the cloned gene. The cloned gene (Fig. 1) will be referred to as POMC I and the other set of fragments as POMC II. The intensity of the bands corresponding to the two POMC genes in the genomic blot (Fig. 2) suggest that POMC II is present in more copies than POMC I. However, in similar experiments with rat liver DNA, bands corresponding to genes I and II were detected and both were of the same intensity (not shown). The difference in intensity found with DNA from HTC cells could well be due to the heteroploidy of these cells<sup>16</sup>. We conclude from these results that there are at least two POMC genes in the rat, as is the case for rat insulin<sup>17,18</sup>.

The rat POMC I DNA sequence was determined (Fig. 3) and it has the same overall organization as the bovine cDNA sequence<sup>7</sup>. The sequence (Fig. 3) is unambiguously oriented with respect to the restriction map (Fig. 1) by the relative position of the *Xho*I and *Pst*I (at amino acids 23–25) sites. The 5' end of the gene is not present in the sequence and is probably not included in the cloned genomic DNA segment. By comparing the rat sequence with the bovine<sup>7</sup>, human<sup>19</sup> and partial rat amino acid sequences<sup>6</sup>, we can deduce that it encodes part of POMC and starts at the 19th codon (alanine) of the precursor (Fig. 3). An IVS interrupts the coding sequence between amino acids 18 and 19 and the junction between this IVS and the coding region is consistent with the consensus sequence proposed for such boundaries<sup>20</sup>. The agreement between the DNA and the partial amino acid<sup>6,21</sup> sequences (underlined in Fig. 3), together with the very high homology between the rat and bovine DNA sequences in regions of known biological function, support the idea that the sequenced POMC I gene could be expressed; stronger evidence will be provided when cDNA copies of rat POMC are sequenced. Furthermore, recent work on pulse-labelled rat pars intermedia POMC suggests that two forms of the precursor differing in their amino acid sequence are expressed<sup>22</sup>.

Comparison of the rat genomic DNA and bovine cDNA sequences reveals that three regions are highly conserved between them: the  $\gamma$ -MSH region (amino acids 19–74), ACTH (amino acids 98–136) and the  $\beta$ -MSH/ $\beta$ -endorphin region (amino acids 160–209). Not only is the postulated<sup>7</sup>  $\gamma$ -MSH sequence (position 51–62) highly conserved between rat, beef<sup>7</sup> and human<sup>19</sup>, but so is the sequence preceding it (position 19–48). Furthermore, one pair of basic amino acids that delimits  $\gamma$ -MSH in the bovine sequence<sup>7</sup> (position 63, 64) is not conserved in the predicted rat sequence, suggesting that if a  $\gamma$ -MSH peptide was made by processing from this precursor it would be 24 amino acids long rather than 12. This is in agreement with the observation that a synthetic 27-amino acid bovine peptide ( $\gamma$ -MSH) shows similar biological activity to tryptic digests of the 16K fragment<sup>8,9</sup>. These results suggest that the peptide(s) encoded in the  $\gamma$ -MSH region of POMC exert some as yet unrecognized biological function(s).

The predicted rat ACTH sequence is closely homologous to the bovine<sup>7</sup> and other known ACTH<sup>23</sup> sequence. Worthy of mention is the asparagine at position 126 (position 29 of ACTH) within the sequence Asn-Glu-Ser: this residue is likely to be the site of glycosylation in rat and mouse ACTH<sup>3,4</sup>.

The predicted rat  $\beta$ -MSH sequence is similar to bovine  $\beta$ -MSH but it does not have the pair of basic amino acids that precedes the bovine sequence. Unless a different type of

processing is involved, this would mean that the only peptides carrying the  $\beta$ -MSH sequence that could be produced from this rat POMC would be the NH<sub>2</sub>-terminal fragment of 38 amino acids ( $\gamma$ -LPH) and  $\beta$ -LPH. Human  $\gamma$ - and  $\beta$ -LPH are the only circulating forms of ' $\beta$ -MSH' immunoreactivity that have been detected<sup>24</sup>. A similar situation might exist in the rat.

Two regions of POMC have diverged considerably between the rat and bovine sequences: those preceding (that is, within the 16K fragment) and following (the amino end of  $\beta$ -LPH) ACTH. In the first region, the rat sequence encodes 8 amino acids less than the bovine sequence and rat  $\gamma$ -LPH would be 22 amino acids shorter than its bovine<sup>7</sup> homologue, as suggested by Mains<sup>25</sup>.

The rat 3'-untranslated region is 60 base pairs shorter than the bovine sequence and only the last 54 base pairs are relatively conserved. This conserved segment contains the sequence AATAAA thought to be involved in poly(A) addition<sup>26</sup> and the sequence ACTTCACAGC related to a sequence often observed just before the poly(A) addition site<sup>27</sup>. A 22-base pair sequence and its almost exact reverse complement (18/22 base pairs) are found at a similar distance from the presumptive poly(A) addition site in the rat and bovine 3'-untranslated regions (indicated by arrows in Fig. 3).

The observation that the bulk of the coding sequence for POMC is uninterrupted by an intervening sequence in the cloned genomic DNA fragment is of interest. The genomic

**Fig. 2** Genomic DNA hybridization. Rat DNA isolated from HTC cells was digested with restriction enzymes and electrophoresed on a 0.8% agarose gel. The transfer to nitrocellulose and the hybridization were done as described in Fig. 1 legend. The two right lanes contain DNA size markers run on the same gel. They are: *Eco*RI-digested pWB91 (11.5 kilobases)<sup>27</sup>, *Eco*RI-digested ColE1 (6.3 kilobases), *Eco*RI-digested pBR322 (4.3 kilobases) and the products of pBR322 digestion with *Ava*I and *Hind*III (2,483, 1,104 and 722 base pairs, respectively)<sup>28</sup>. The 144-base pair mouse cDNA fragment cloned in pBR322 was nick translated<sup>15</sup> and used as probe. *Eco*RI (RI) DNA fragments of 13 and 5.5 kilobases, and two *Hind*III (H3) fragments of 4.4 and 3.8 kilobases, hybridize to the probe. The 3.8-kilobase *Hind*III fragment is not digested by *Eco*RI and corresponds in size and restriction map to the one present in the cloned gene. Both *Bam*HI (Bam) and *Xba*I (Xba) produce broad bands (probably doublets) at about 5.4–5.8 and 6.3–6.7 kilobases, respectively. Another weakly hybridizing *Xba*I fragment of about 2.8 kilobases does not correspond to any fragment found in the cloned gene. Finally, the double digest of *Hind*III + *Xba*I generates a 2.6-kilobase fragment as in the cloned gene and a more intensely hybridizing band at about 4.4 kilobases (Kb).

**Fig. 3** DNA sequence of the rat POMC gene. The DNA nucleotide sequence of the cloned rat POMC gene was determined by the dideoxy chain termination method<sup>29</sup> using single-stranded viral DNA from M13mp2 (refs 40, 41) subclones as templates and the synthetic dodecanucleotide d(TCAGCAGCTTGT) complementary to the phage sequence as a primer. The 2.6-kilobase *Xba*I+*Hind*III fragment that hybridizes to the cloned mouse cDNA probe (Fig. 1) was digested with one of four restriction enzymes (*Hae*III, *A*luI, *Hpa*II or *Rsa*I) for subcloning in M13mp2. These restriction fragments were blunt-end ligated into the 'filled-in' *Eco*RI site of the M13mp2 vector, introduced into the appropriate *Escherichia coli* strain by transformation, and clones containing fragments of the POMC gene identified by plaque hybridization<sup>12</sup> with a probe made from the 2.6-kilobase *Xba*I+*Hind*III fragment. Single-stranded DNA was prepared from 1-ml cultures of each positive candidate<sup>42</sup> and one dideoxy sequencing reaction (ddTTP) was carried out on each to identify similar clones. A representative of each type of recombinant phage obtained was fully sequenced. The complete sequence was deduced by computer-assisted sequence overlap of different clones. More than 95% of the sequence presented was read from both strands and confirmed using different clones, except for the sequence following the *Hae*III site in the 3'-untranslated region, which was read by priming only from the *Hpa*II site at the position of amino acids 154–155. This part of the sequence is therefore less reliable than the rest. The detailed sequencing data are available to investigators on request. The DNA nucleotide sequence and its predicted translation product are shown in comparison with the published bovine cDNA sequence<sup>7</sup>. The amino acid sequence is not numbered from the NH<sub>2</sub> terminus of ACTH as in ref. 7 but from the NH<sub>2</sub> terminus of POMC, which has been determined recently by partial amino acid sequencing of the human<sup>18</sup> and rat<sup>6</sup> polypeptides. The only difference between the predicted amino acid sequence and that determined by Gianoulakis *et al.*<sup>21</sup> is at position 144 (position 6 of  $\beta$ -LPH): they found a phenylalanine whereas the DNA sequence predicts a glutamine. As this residue is the only one where the two sequences do not agree it may be due to a strain difference; one set of data is from Sprague-Dawley and the other (presented here) from Long-Evans rats. The boxed pairs of basic amino acids represent known (solid line) or possible (dashed line) sites of precursor processing.

DNA encoding the functional and structural domains of immunoglobins has been shown to be interrupted by IVSs at the junction between these domains and it was suggested that such gene organization could reflect the evolution of these genes<sup>28–30</sup>; a similar argument was made for the globin genes<sup>31,32</sup>. The three MSH sequences in POMC suggest the evolution of the precursor by duplications of an ancestral gene. Although there are no evolutionary data it is tantalizing to speculate that the precursor's function as a hormone is responsible for its evolution by duplication rather than by IVS-mediated joining of sequences encoding different structural domains. However, it is possible that the cloned gene lost an IVS present in an ancestral gene. The structural constraints imposed by the function of proteins like the immunoglobulins and globins are very different from those exerted on a hormone precursor like POMC. The addition of a new structural domain to the latter would be very unlikely to result in new hormonal activity because this would require the near concomitant appearance of a new receptor molecule on a target cell. On the other hand, evolution of the hormone precursor by duplication would allow the maintenance of the duplicated segment and its slow drifting to another hormonal activity.

Since submission of this manuscript, A. C. Y. Chang *et al.*<sup>33</sup> have published a genomic DNA sequence encoding the same portion of human POMC. The human gene is interrupted by an IVS at about the same position in the coding region and the human sequence diverges from the bovine in the same regions as the rat DNA sequence. Also, Nakanishi *et al.*<sup>34</sup> have published the protein-coding sequence of the bovine ACTH- $\beta$ -lipotropin precursor gene, and find that it is split near the signal peptide region by an intervening sequence of about 2.2 kilobase pairs.

We thank James L. Roberts and Beth Schachter for gifts of AtT-20 poly(A)-containing RNA and HTC DNA, respectively, our colleagues John Fiddes, David Moore, Robert Hallowell and Chi Nguyen-Huu for helpful discussions and critical reading of this manuscript, and Brett McCabe for typing the manuscript. The amino acid sequencing data were made available to us before publication by Dr Michel Chretien. J. D. is supported by a Centennial Fellowship of the MRC of Canada. H.M.G. is an investigator of the Howard Hughes Medical Institute. This work was supported by NIH grant CA 14026.

## Selective processing of $\beta$ -endorphin in regions of porcine pituitary

D. G. Smyth & S. Zakarian

National Institute for Medical Research, The Ridgeway, Mill Hill, London NW7 1AA, UK

The prohormone of  $\beta$ -endorphin is unusual in that it is the precursor of more than one biologically active peptide<sup>1-3</sup> (Fig. 1). The activation of this prohormone, to produce corticotropin (ACTH),  $\alpha$ -melanotropin ( $\alpha$ -MSH) and  $\beta$ -endorphin, would seem to be relatively complex as its processing pattern is known to differ between tissues. Thus ACTH is produced in the anterior pituitary whereas  $\alpha$ -MSH is formed in the pars intermedia<sup>4,5</sup>; similarly, lipotropin and  $\beta$ -endorphin seem to predominate in the anterior pituitary whereas  $\beta$ -endorphin alone has been thought to be the principal component in the pars intermedia. We report here a study of the distribution of  $\beta$ -endorphin-related peptides in various regions of porcine pituitary. The main products in the anterior pituitary were lipotropin and the potent analgesic form of  $\beta$ -endorphin, whereas the main products in the pars intermedia were the inactive lipotropin C'-fragment and its N-acetyl derivative. Thus the processing of the C-terminal region of the  $\beta$ -endorphin prohormone differs markedly between the two regions of porcine pituitary.

We concentrated on the processing of the C-terminal region of the prohormone by studying the distribution of four peptides related to  $\beta$ -endorphin: the C'-fragment of the prohormone

( $\beta$ -endorphin, lipotropin residues 61-91), the C'-fragment (lipotropin residues 61-87), the  $\alpha$ , N-acetyl derivative of the C'-fragment, and the  $\alpha$ , N-acetyl derivative of the C'-fragment<sup>6-8</sup>. These peptides have a similar molecular size and are generally identified and measured together as a single immunoreactive component<sup>9,10</sup>. Their biological activities, however, differ strikingly:  $\beta$ -endorphin has potent analgesic properties<sup>11,12</sup> whereas the C'-fragment is 500 times less potent<sup>13</sup> and the acetyl peptides are inactive<sup>8,14</sup>. The processing of the  $\beta$ -endorphin prohormone to produce active or inactive endorphins may therefore have physiological significance and because the processing could vary between tissues it is clearly important that the individual peptides should be differentiated.

We studied the distribution of  $\beta$ -endorphin-related peptides in the anterior pituitary and pars intermedia plus posterior pituitary by extracting the peptides from dissected regions of porcine pituitary glands. The products were resolved by gel filtration, ion exchange chromatography and high pressure liquid chromatography (HPLC). To locate the eluted peptides (and to allow estimation of peptide recovery) the four known  $\beta$ -endorphin-related peptides, obtained by isolation from porcine pituitary<sup>7,8</sup>, were radioiodinated and trace amounts added to the solvent used to extract the tissues. The peptides resolved by column chromatography were detected and measured by radioimmunoassay (RIA) using an antiserum raised against porcine  $\beta$ -endorphin<sup>15</sup>, and further evidence for the identity and concentrations of the peptides was obtained by comparison of elution positions and peak heights on HPLC with those produced by reference peptides. This extensive chromatographic procedure was necessary because of the complexity of the mixture of pituitary peptides, and because each of the four  $\beta$ -endorphin-related peptides reacted with the  $\beta$ -endorphin antiserum<sup>15</sup>, which prevented their differential estimation by immunoassay of the tissue extracts without previous fractionation.

Gel filtration of the peptides extracted from the anterior pituitary revealed two fractions which differed in molecular size (Fig. 2a); the first emerged in the position of porcine lipotropin and the second contained peptides that eluted in the position of porcine  $\beta$ -endorphin. Resolution of the  $\beta$ -endorphin fraction by ion exchange chromatography showed that the main immunoreactive component co-chromatographed with <sup>125</sup>I-labelled porcine  $\beta$ -endorphin (Fig. 3) and its identity was confirmed by comparison with authentic porcine  $\beta$ -endorphin during HPLC. There was, in addition, a small amount (<4% of the  $\beta$ -endorphin) of other immunoreactive peptides which were chromatographically identical to peptides present in high concentration in the pars intermedia. Thus, apart from these minor components, the principal C-terminal fragments of the  $\beta$ -endorphin prohormone in porcine anterior pituitary are lipotropin and  $\beta$ -endorphin, with  $\beta$ -endorphin accounting for nearly 50% of the total immunoreactive material.

Gel filtration of the peptides extracted from the pars intermedia and posterior pituitary showed a negligible amount of

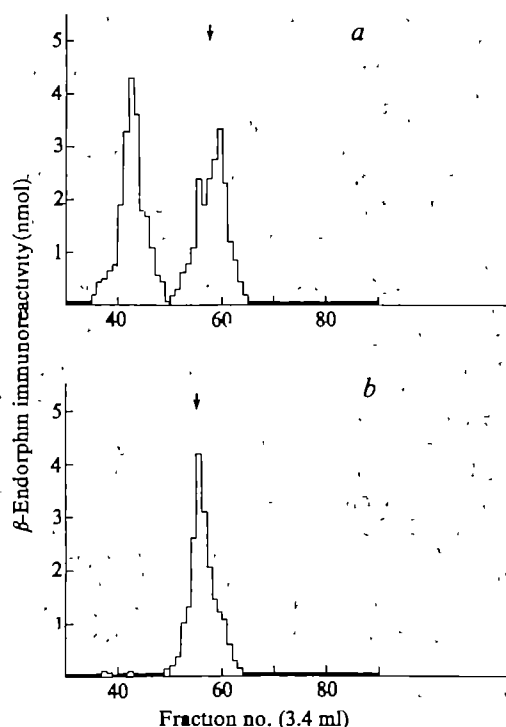

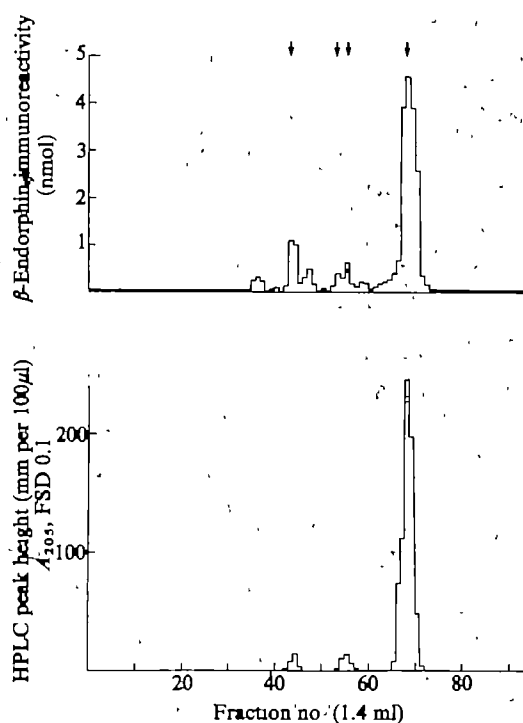

Fig. 1 Schematic representation of the biologically active sections of the 31K prohormone of  $\beta$ -endorphin (according to Nakanishi *et al.*<sup>3</sup>). The numbers represent residue positions in the sequence of the bovine molecule. Each of the peptides indicated is flanked by pairs of basic residues in the prohormone sequence. Several of the prohormone fragments exist both in acetylated and unacetylated forms<sup>8</sup>.

lipotropin or 31K prohormone, but there was a substantial quantity of immunoreactive peptide with the approximate molecular size of  $\beta$ -endorphin (Fig. 2b). The  $\beta$ -endorphin-containing fraction was resolved into at least six components by chromatography on SP-Sephadex C25 (Fig. 4)—note that the biologically active form of  $\beta$ -endorphin (Peak VI) was only a minor component, representing less than 7% of the immunoreactive peptides. Four of the six peptides (Peaks II, IV, V and VI) co-chromatographed with the corresponding radiolabelled markers and their chromatographic behaviour on HPLC was indistinguishable from the corresponding reference peptides ( $\alpha$ ,  $N$ -acetyl C'-fragment, C'-fragment,  $\alpha$ ,  $N$ -acetyl  $\beta$ -endorphin and  $\beta$ -endorphin). Two of the remaining peptides (Peaks I and III), which were not accompanied by radioactive markers, were found to co-chromatograph on SP-Sephadex C25 and on HPLC with peptides formed by mild reaction of C'-fragment or  $\alpha$ ,  $N$ -acetyl C'-fragment with acetic anhydride *in vitro* and did not correspond to products generated by acetylation of  $\beta$ -endorphin. On this basis the two peptides seem to be an  $\epsilon$ ,  $N$ -acetyl derivative of the C'-fragment (Peak III) and an  $\epsilon$ ,  $N$ -acetyl derivative of  $\alpha$ ,  $N$ -acetyl C'-fragment (Peak I).

**Fig. 2** Gel filtration of peptides related to  $\beta$ -endorphin extracted from *a*, porcine anterior pituitary and *b*, porcine pars intermedia plus posterior pituitary. Acid-acetone extraction (acetone/H<sub>2</sub>O/hydrochloric acid, 40/6/1) was carried out at 4 °C on four anterior pituitary lobes or pars intermedia plus posterior pituitary lobes, dissected 20 min *post mortem*. Radiolabelled marker peptides were added before extraction ( $\alpha$ ,  $N$ -acetyl C'-fragment, C'-fragment,  $\alpha$ ,  $N$ -acetyl  $\beta$ -endorphin and  $\beta$ -endorphin were labelled by treatment of 1  $\mu$ g of peptide with 100  $\mu$ Ci of <sup>125</sup>I and  $\sim 6 \times 10^4$  c.p.m. of each peptide was used). The extract was centrifuged at 15,000 r.p.m. for 60 min, acetone was removed by concentration *in vacuo* at 20 °C, and the residual solution diluted in 50% acetic acid in preparation for gel filtration on a Sephadex G75 column (70  $\times$  2.5 cm) in 50% acetic acid. The elution position of the <sup>125</sup>I-labelled  $\beta$ -endorphin related marker peptides is indicated by an arrow. Aliquots (0.25  $\mu$ l) from the anterior pituitary fractions and (0.5  $\mu$ l) from the pars intermedia fractions were immunoassayed using an antiserum to  $\beta$ -endorphin: the antiserum did not cross-react with  $\gamma$ -endorphin or methionine enkephalin but reacted with the  $\alpha$ ,  $N$ -acetyl derivative of  $\beta$ -endorphin and the  $\alpha$ ,  $N$ -acetyl derivative of the C'-fragment, with affinity equal to that of the respective unacetylated parent peptides<sup>15</sup>.

**Fig. 3** Ion exchange chromatography of peptides with the molecular size of  $\beta$ -endorphin, obtained by gel filtration of porcine anterior pituitary extracts. After removal of the acetic acid *in vacuo* at 20 °C from the fractions obtained by gel filtration, chromatography of the peptides was performed on a column (60  $\times$  0.6 cm) of SP-Sephadex C25 in 50% acetic acid with a linear gradient from 0 to 0.6 M sodium chloride, mixer volume 100 ml. The elution positions of the radiolabelled reference peptides ( $\alpha$ ,  $N$ -acetyl C'-fragment, C'-fragment,  $\alpha$ ,  $N$ -acetyl  $\beta$ -endorphin and  $\beta$ -endorphin) are indicated respectively from left to right by the arrows. Aliquots (0.5  $\mu$ l) of the column fractions were dried *in vacuo* and immunoassayed with a  $\beta$ -endorphin antiserum<sup>15</sup>; the amounts of the peptides determined by RIA shown have not been corrected for their immunoreactivities. A second series of aliquots (20–400  $\mu$ l), taken from fractions shown to contain  $\beta$ -endorphin related peptides by RIA, were monitored by HPLC (Waters Associates, Inc.) using a C<sub>18</sub> Bondapak column (30  $\times$  0.4 cm) eluted in 0.01 M hydrochloric acid with a linear gradient (15 min) from 25–40% acetonitrile. The amounts of the peptides shown were determined from the optical density at 205 nm given by the peptide peak occurring at the position of the appropriate unlabelled reference peptide, compared with the peak heights given by known amounts of the marker peptide.

These results show that in the anterior pituitary lipotropin is accompanied by the potent analgesic form of  $\beta$ -endorphin whereas in the pars intermedia the inactive peptides, lipotropin C'-fragment and its  $N$ -acetyl derivative, are the major products. Thus the processing of the C-terminal region of the  $\beta$ -endorphin prohormone differs markedly in the two regions.

The relative amounts of  $\beta$ -endorphin and the C'-fragment, together with their acetylated derivatives, may reflect the activity of proteolytic enzymes with specificity for the respective cleavage sites in lipotropin, the Lys-Arg-Tyr residues at positions 59, 60 and 61 and the Lys-Lys-Gly residues at positions 88, 89 and 90. It may be concluded that the specificity of the processing enzymes in the anterior pituitary differs from that in the pars intermedia. Furthermore, the acetylation of  $\beta$ -endorphin and the C'-fragment takes place almost exclusively in the pars intermedia<sup>16,17</sup>. It is likely that the acetyl endorphins are formed concomitantly with  $\alpha$ -MSH because these acetylated peptides occur in the same region of pituitary (ref. 5 and this communication) and originate as fragments of the same prohormone. Note that the acetyl group is important for the melanotropic activity of  $\alpha$ -MSH<sup>18</sup> but it renders  $\beta$ -endorphin inactive as an opiate. It seems therefore that activation of one

section of the ACTH-endorphin prohormone can be accompanied by inactivation of another.

In an earlier report<sup>15</sup>, we had concluded that the same inactive peptide fragments were present in both the anterior lobe and the pars intermedia of rat pituitary. However, it is now clear that this result was due to slight contamination of the anterior region by cells from the pars intermedia and that the processing patterns are very similar in the corresponding regions of pig and rat pituitary<sup>16</sup>. Thus the differential processing mechanisms are conserved across species.

The two regions of porcine pituitary contain approximately equal amounts of the group of  $\beta$ -endorphin-related peptides whereas in the rat the concentration of the peptides in the pars intermedia is nearly two orders of magnitude greater than that in the anterior pituitary. Studies on the significance of these peptides in different species may therefore be useful in obtaining an understanding of the changing physiological role of the pars intermedia during evolution.

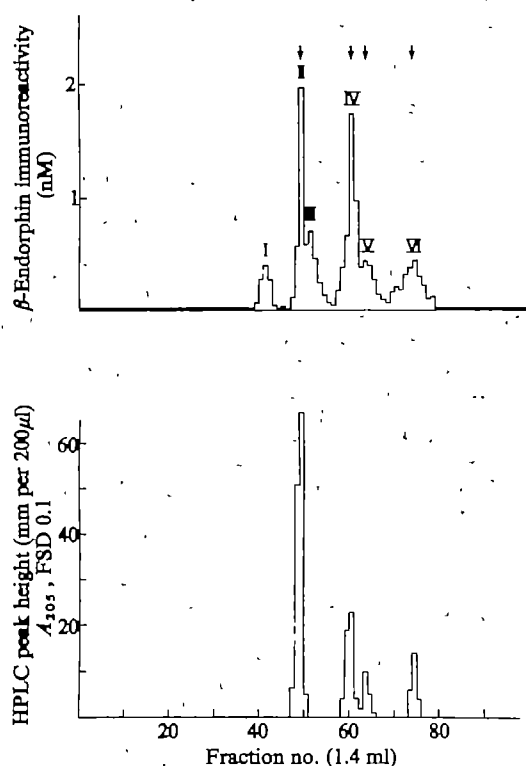

The results of this study demonstrate that specific mechanisms lead to the production of  $\beta$ -endorphin in its opiate active form in porcine anterior pituitary. It is known that ACTH is elaborated in the anterior pituitary and is formed from the same prohormone as  $\beta$ -endorphin; thus two biologically active peptides (ACTH and  $\beta$ -endorphin) are generated together with a potential for synergistic action. However, in the pars intermedia,  $\alpha$ -MSH is accompanied principally by forms of  $\beta$ -endorphin that have been inactivated by proteolysis or acetylation. It

therefore seems that different processing mechanisms acting on the multifunctional prohormone are available to select the appropriate biological activity required in different regions of the pituitary.

We thank Derek Massey and Kamela Maruthainar for technical assistance.

**Fig. 4** Ion exchange chromatography of peptides with the molecular size of  $\beta$ -endorphin present in porcine pars intermedia plus posterior pituitary. After gel filtration of the tissue extract on Sephadex G75 in 50% acetic acid, the  $\beta$ -endorphin fraction, localized by RIA and by measuring the radioactivity of the marker peptides, was concentrated *in vacuo* at 20°C and added to a column (60×0.6 cm) of SP-Sephadex C25 in 50% acetic acid. Chromatography was performed as in Fig. 3 legend and the elution positions of the four radiolabelled reference peptides ( $\alpha$ , N-acetyl C-fragment, C'-fragment,  $\alpha$ , N-acetyl  $\beta$ -endorphin and  $\beta$ -endorphin) are shown from left to right by arrows. Aliquots (0.5  $\mu$ l) of the eluted fractions were dried *in vacuo* and RIA was carried out using the  $\beta$ -endorphin antiserum. A second series of aliquots (20–400  $\mu$ l) taken from the fractions that contained  $\beta$ -endorphin immunoreactive peptides, were monitored by HPLC (see Fig. 3 legend) and compared with appropriate reference peptides.

## Expression of H-2, laminin and SV40 T and TASA on differentiation of transformed murine teratocarcinoma cells

B. B. Knowles, S. Pan, D. Solter, A. Linnenbach, C. Croce & K. Huebner

The Wistar Institute, 36th Street at Spruce, Philadelphia, Pennsylvania 19104

Murine embryonal carcinoma cells (ECCs) do not express antigens of the major histocompatibility complex (H-2)<sup>1,2</sup>, but do express cell-surface molecules shared with early embryos<sup>3</sup>. ECCs are also characterized by their insusceptibility to infection by various oncogenic viruses<sup>4,7</sup>, and their ability to differentiate into a variety of adult cell types<sup>8</sup>. Differentiation of ECCs *in vitro* can occur spontaneously or can be induced<sup>9–12</sup>. On exposure to retinoic acid the ECC line F9 (ref. 13) differentiates into cells which have the characteristics of parietal endoderm<sup>10,14</sup>. When ECCs are exposed to simian virus 40 (SV40), the SV40 tumour (T) antigen is not expressed<sup>4</sup>, although the virus genome reaches the nucleus<sup>15</sup>, and a primary transcript of the SV40 A gene is made<sup>16</sup>. However, following exposure to retinoic acid, the differentiated cells, like most mouse somatic cells, are susceptible to SV40 abortive infection and synthesize large T and small t antigens<sup>17</sup>. To monitor the molecular events associated with the expression of the SV40 A gene on differentiation, we have constructed an ECC line (F9 12-1) containing a single integrated copy of the SV40 genome<sup>18</sup>. This was accomplished by introducing a recombinant plasmid consisting of pBR322 linked to the herpes simplex type 1 thymidine kinase gene and SV40 genome<sup>19</sup> into a thymidine kinase-deficient F9 cell line<sup>19</sup>. We report here that in F9 12-1 cells exposed to retinoic acid, synthesis of the SV40 A gene product(s), T and tumour-associated specific antigens (TASA), parallels the appearance of the normal hallmarks of differentiation in this cell line, H-2 antigens and the basement membrane protein laminin<sup>20</sup>.

F9 12-1 cells are morphologically identical to murine ECCs. In our experiments (Table 1), we were unable to find any unequivocally SV40 T antigen-positive nuclei; however, because it is difficult to estimate nuclear fluorescence in ECCs due to their characteristic growth in clumps of rounded cells, we

**Table 1** Immunofluorescent assay for detection of antigenic determinants specific to stem cells (SSEA-1), differentiated cells (H-2D<sup>b</sup>) and SV40 T antigen

| Cell line                        | Days following exposure to RA | % Positive cells |                   |                 |

| F9 12-1 clone a (differentiated) |                               | 0                | 100               | 98              |
| K4RSV                            |                               | 0                | 100               | 95              |
| K5RSV                            |                               | 0                | 0                 | 97              |

A single-cell suspension of F9 12-1 was placed in 60-mm plastic Petri dishes (Falcon) containing a glass coverlip and cultured in RPMI 1640 with 10% fetal bovine serum (FBS) and  $5 \times 10^{-7}$  M retinoic acid (RA) (*all trans*; Eastman)<sup>10,14</sup>. The medium was replaced with the same medium without retinoic acid 16 h before assay. F9 12-1 and F9 12-1 clone a were cultured in RPMI with 10% FBS. Cells were resuspended by exposure to 0.25% trypsin in phosphate-buffered saline (PBS) containing 0.1 M EDTA. SSEA-1 expression was determined by indirect immunofluorescent assay using monoclonal antibody to SSEA-1 diluted 1:200 (100  $\mu$ l per  $2 \times 10^5$  cells) as described<sup>21</sup> elsewhere. Rabbit IgG, anti-mouse IgG (heavy and light chain specific) (RAMIG) tagged with fluorescein isothiocyanate (FITC) (Cappel) served as the developing reagent; cells were mounted in equal parts of Dulbecco's modified PBS and glycerol on glass slides, with coverlips, and viewed using a Leitz Ortholux microscope with epifluorescence and appropriate filters. Cell suspensions were exposed to a 1:100 dilution of monoclonal antibody B22-249R which detects the H-2D<sup>b</sup> private-specificity 2 (ref. 22). Following exposure to RAMIG-FITC and mounting, cells were scored for fluorescence (see above).

\* Coverlips were washed three times with Dulbecco's modified PBS and fixed by 5 min exposure to  $-20^\circ\text{C}$  acetone and dried. The coverlips were then overlaid with monoclonal antibody to SV40 T antigen, washed and exposed to RAMIG-FITC. Coverlips were mounted in Uvinert aqueous mounting medium (Gurr) and scored for the presence of nuclear fluorescence. In all cases an equivalent amount of IgG from the P3 X63 Ag8 (ref. 23) cell line was used as a control.

cannot exclude the presence of an occasional SV40 T antigen-positive cell. Like all murine ECCs, the F9 12-1 cell does not express H-2D<sup>b</sup> (Table 1). Although a very low percentage of the cells are weakly fluorescent following reaction with monoclonal antibody to an H-2D<sup>b</sup> antigenic determinant (Table 1), a similar number of fluorescent cells are found when the F9 12-1 cells are incubated with immunoglobulin from the P3X63 Ag8 myeloma cell line. We were also unable to detect those determinants of the H-2K<sup>b</sup> or D<sup>b</sup> molecules recognized by murine cytotoxic T lymphocytes (CTLs) sensitized by allogeneic immunization (Fig. 1). In addition, no SV40 TASA associated with H-2K<sup>b</sup> or H-2D<sup>b</sup> and recognized by SV40-sensitized H-2<sup>b</sup>-restricted CTLs, are expressed. Murine ECCs are characterized by the expression of a stage-specific embryonic antigenic determinant (SSEA-1) which is also found on murine preimplantation embryos beginning at the 8-cell stage and on cells of the inner cell mass<sup>25</sup>. SSEA-1 is secreted into the medium of ECCs and can be detected on 80–100% of all murine ECCs tested. F9 12-1 reacts with the monoclonal antibody that defines the SSEA-1 antigenic determinant (Table 1). A small amount of basement membrane protein is synthesized by F9 cell lines<sup>26</sup>. Antibody to basement membrane protein reacts with a small proportion of cells on the periphery of some of the clumps of the F9 12-1 culture (Fig. 2a). Thus on the basis of morphology, surface-antigen expression and SV40 A gene expression, the F9 12-1 cell seem to behave as other ECCs.

Within 2 days of exposure to retinoic acid some of the F9 12-1 cells assume a flattened, epitheloid morphology. A small percentage of cells express H-2 antigens and the SV40 A gene product(s) T and TASA, are detectable (Table 1, Fig. 1). Most of the cells in these cultures retain the stem cell characteristics. As the cultures are maintained in retinoic acid, differentiation proceeds and after 1 week approximately half the cells morphologically resemble parietal endodermal cells, are synthesizing laminin (Fig. 2b), and express H-2 and SV40 T and TASA.

After 14 days, most of the cells are differentiated, with only a small per cent SSEA-1-positive and over 90% SV40 T- and TASA-positive. These cells also synthesize both laminin and H-2, an indication that cells with the characteristics of parietal

**Fig. 1** Detection of H-2K, H-2D and SV40 TASA in association with H-2K<sup>b</sup> and H-2D<sup>b</sup> in F9 12-1 cells following exposure to retinoic acid. Cells were seeded into 60-mm Petri dishes in RPMI 1640 with 10% FBS and retinoic acid ( $5 \times 10^{-7}$  M) (ref. 10). F9 12-1 clone a cells, exposed 120 d previously to retinoic acid, were grown in RPMI 1640 with 10% FBS. Sixteen hours before assay the cells were re-fed with RPMI 1640 and 10% FBS containing  $^{51}\text{Cr}$ -labelled sodium chromate (NEZ030; 150 Ci per 5 ml). Control target cells (not shown) were SV40-transformed cell lines derived from C57B 10/ScSn congenic mice; K4RSV (H-2K<sup>b</sup>D<sup>b</sup>), K5RSV (H-2K<sup>b</sup>D<sup>b</sup>), LB10SV (H-2K<sup>b</sup>D<sup>b</sup>) and KD2SV (H-2K<sup>b</sup>D<sup>b</sup>) (ref. 24). The  $^{51}\text{Cr}$ -labelled cells were washed, resuspended and incubated for 7 h at a concentration of  $2 \times 10^4$  cells per 0.2 ml, with lymphocytes. Percentage  $^{51}\text{Cr}$ -release was calculated after  $\gamma$  counting of the supernatant fluid and the cells as described elsewhere<sup>24</sup>. Cytotoxic effector cells specific for SV40 TASA associated with H-2K<sup>b</sup> and H-2D<sup>b</sup> were obtained by immunization of B10.A(5R) and B10.A(4R) mice, respectively, with  $10^7$  infectious units of SV40 in each of the hind footpads. One week after immunization, the popliteal lymph nodes were excised, single-cell suspensions prepared and placed in Dulbecco's modified Eagle's minimal essential medium (supplemented with 10% FBS), 2-mercaptoethanol ( $2 \times 10^{-5}$  M), sodium pyruvate (1 mM), Eagle's non-essential amino acids, penicillin and streptomycin) at a concentration of  $10^7$  cells per 10 ml in 25-cm<sup>2</sup> plastic tissue culture flasks (Falcon), and incubated at  $37^\circ\text{C}$ , 5%  $\text{CO}_2$  in humidified air for 3 d before assay<sup>24</sup>. Effector cells specific for H-2K<sup>b</sup> and H-2D<sup>b</sup> were obtained by *in vitro* stimulation of BALB/c AnICR (H-2K<sup>b</sup>D<sup>b</sup>) splenic lymphocytes with irradiated (7,000R) splenic lymphocytes from B10.D2 (R107) (H-2K<sup>b</sup>D<sup>b</sup>) and B10.HTG (H-2K<sup>b</sup>D<sup>b</sup>), respectively. BALB/c cells ( $5 \times 10^6$ ) were incubated with stimulator cells ( $2 \times 10^5$ ) in 2 ml medium per well of a 24-well Linbro plate. After incubation for 6 d at  $37^\circ\text{C}$  in a 5%  $\text{CO}_2$  humidified atmosphere, the cells were either re-stimulated *in vitro* (by the addition of  $2 \times 10^6$  irradiated stimulator cells to  $5 \times 10^6$  viable cells 2 ml medium) and collected after 5 d or used as effectors immediately. Effector to target cell ratio 10:1 for anti-SV40 TASA effectors and 100:1 for anti-H-2 effectors.

**Fig. 2** Immunofluorescent assay for the presence of laminin. Coverslips were fixed (as described in Table 1 legend) and exposed to rabbit anti-mouse basement membrane protein (anti-peak 1) serum<sup>27</sup> (provided by Dr Barry Pierce) and absorbed before use with mouse 3T3 cells (1:12 dilution). FITC-tagged goat IgG anti-rabbit IgG served as the developing reagent. *a*, F9 12-1 before exposure to retinoic acid (RA); *b*, 10 d following exposure to RA; *c*, F9 12-1 clone a.

endoderm express antigens of the major histocompatibility complex.

A differentiated cell line, F9 12-1 clone a, which was cloned from retinoic acid-treated F9 12-1 4 months earlier, was included in these experiments. All cells of this clone express H-2, are SSEA-1-negative, T antigen-positive and express SV40 TASA in association with both H-2K<sup>b</sup> and H-2D<sup>b</sup>. In contrast to the cells monitored for 16 days following retinoic acid treatment, laminin was not detectable in F9 12-1 clone a (Fig. 2c) and the cells appeared fibroblastic. We have previously isolated a differentiated clone (F9 AC clone 9) from retinoic acid-treated F9 cells which has retained its parietal endoderm phenotype for 2 yr in culture. It is possible that, following exposure to retinoic acid, a minor population of fibroblastic cells is always induced and that a representative of these cells gives rise to F9 12-1 clone a. Alternatively, parietal endoderm-like cells may be the only differentiated cells resulting from retinoic acid treatment of F9 cells. However, due to the presence of the SV40 genome, the parietal endoderm phenotype may be transitory with all stable, transformed cells appearing fibroblastic. Experiments are being done to investigate these possibilities.

Recognition of SV40 TASA by virus-specific cytotoxic effector T cells is contingent on expression of the H-2K and D gene products. In contrast to the ECC line PCC3A/1, which does not express H-2 when induced to differentiate by exposure to hexamethylene bisacetamide<sup>11</sup>, each F9 cell which differen-

tiated cells can independently express the H-2K and H-2D gene observed that somatic cell hybrids between F9 and differentiated cells can independently express the H-2K and H-2D gene products<sup>19</sup>, although the mechanism by which this regulatory event occurs remains undefined. Differentiation of the F9 12-1 cell, however, is accompanied by simultaneous expression of both H-2K and H-2D gene products (Fig. 1). This conclusion is based on results with cytotoxic effector cells specific for H-2K<sup>b</sup> and H-2D<sup>b</sup>. In addition, because recognition of SV40 TASA in mice of the H-2<sup>b</sup> haplotype occurs in association with both H-2K<sup>b</sup> and H-2D<sup>b</sup> (ref. 24), the results with cytotoxic effector cells specific for H-2K<sup>b</sup>-SV40 TASA and H-2D<sup>b</sup>-SV40 TASA indicate simultaneous expression of the H-2K<sup>b</sup> and H-2D<sup>b</sup> gene products. Because expression of the H-2 determinants is necessary for CTL recognition of foreign antigens on the cell surface<sup>28</sup>, it is impossible from inspection of the data in Fig. 1 to determine if the SV40 TASA and H-2 antigens appear simultaneously or sequentially. From the data obtained at 2 and 4 days after retinoic acid induction (Table 1), it can be surmised that the H-2D<sup>b</sup> gene product is expressed (and SSEA-1 suppressed) at an earlier time than the SV40 A gene products. However, SV40 T antigen is synthesized in cytoplasm but can only be detected by immunofluorescent techniques following accumulation in the nucleus<sup>29</sup>. Furthermore, cell-surface antigens are more readily detectable by the methods used, so we feel this difference in time of appearance is artefactual. We therefore propose that, following induction of differentiation, there is simultaneous activation of a series of genes, perhaps through the pleiotropic action of a single gene product (for example RNA splicing enzymes<sup>16,17</sup>). Alternatively, a single regulatory event could lead to the synthesis of factors necessary for expression of each of the gene products investigated. The organization of the SV40 genome in relation to the cellular genome in the F9 12-1 cell, the F9 12-1 retinoic acid-treated cells and the F9 12-1 clone a cell is identical (A.L. and K.H., unpublished).

Finally Lehman and Friedrich<sup>30</sup> report that when ECCs are infected with SV40 and then induced to differentiate, SV40 A gene products are not expressed. Free unintegrated SV40 viral DNA was found in these ECCs, and in the differentiated cells derived from them, that was capable of infecting permissive monkey kidney cells, although integrated viral DNA was not detected. The F9 12-1 cells contain integrated SV40 genomes<sup>18</sup> and when they differentiate the SV40 A gene products are expressed. A comparison of these results suggests that integration of the SV40 genome is a prerequisite for the expression of SV40 gene products.

The formation of individual functional mRNA sequences in higher organisms requires many steps in addition to transcription. These include RNA splicing, polyadenylation, base modification, transport from nucleus to cytoplasm and assembly into polyribosomes. Various control mechanisms must also operate. These will function on a quantitative basis to account for the differing frequency of the various classes of cytoplasmic mRNAs, and also on a qualitative basis, because in higher organisms not all the nuclear poly(A)-containing RNA molecules are found in a cytoplasmic poly(A)-containing RNA population from the same tissue<sup>1–10</sup>. During our studies on the mechanisms controlling the accumulation of the poly(A)-containing RNA sequences which occur with high and moderately high frequency in the cytoplasm of the lactating guinea pig mammary gland, it became apparent that >75% of the 20,000 or so poly(A)-containing nuclear RNA sequences were not found in the cytoplasmic poly(A)-containing RNA fraction<sup>4</sup>. Here we demonstrate that many of the poly(A)-containing RNA sequences retained in the nucleus of the lactating guinea pig mammary gland are also present in the nucleus and cytoplasm of the liver of the male guinea pig. These observations provide new evidence for a predominant role of post-transcriptional mechanisms in the regulation of structural gene expression in guinea pig tissue.

Comparison of the base complexity of nuclear and cytoplasmic poly(A)-containing RNA sequences isolated from the lactating guinea pig mammary gland and the male guinea pig liver, demonstrate that the number of different sequences expressed in the nuclear population was similar, but that nearly three times as many poly(A)-containing RNA sequences were present in the cytoplasm of the liver as in the cytoplasm of the mammary gland (Table 1, Fig. 1a). Cross-hybridization studies between the two nuclear poly(A)-containing RNA populations revealed that although each contained similar sequences, there were striking quantitative differences (Fig. 1a). Subsequent hybridization studies using mammary gland nuclear cDNA fractionated into hybridization probes for high- and low-frequency poly(A)-containing RNA sequences showed that sequences present at high frequency in the lactating mammary gland (a group of up to 30 different sequences including the milk proteins<sup>4,5</sup>) were present at very low frequency in the liver (Fig. 1b). In contrast, the most complex population, consisting of sequences which occurred at low frequency in the lactating mammary gland, were present in the liver in comparable amounts (Fig. 1b).

Cross-hybridization studies using mammary gland<sup>4</sup> and liver RNA populations<sup>6</sup> demonstrate that the cytoplasmic poly(A)-containing RNA sequences are all represented within the nuclear poly(A)-containing RNA populations from the same

tissues. This observation, together with the fact that the base complexity of the liver cytoplasmic population is considerably greater than the equivalent lactating mammary gland population suggested that some of those sequences retained in the nucleus of the mammary gland might represent sequences expressed as cytoplasmic poly(A)-containing sequences in liver.

To test this, a cDNA probe representative of those mammary gland poly(A)-containing RNA sequences retained in the nucleus, was hybridized to liver nuclear and cytoplasmic poly(A)-containing RNA. This resulted in maximum hybridization of the probe to nuclear RNA with the expected kinetics, but also significant hybridization to the cytoplasmic RNA population (Fig. 2). We estimate that 3,000–4,000 of those sequences retained in the nucleus of the lactating mammary gland were present in the cytoplasm of the liver. This hybridization cannot be an artefact due to contaminating nuclear sequences within the liver cytoplasmic population because this proportion of the hybridization probe hybridized faster to the liver cytoplasmic poly(A)-containing RNA population than to the liver nuclear poly(A)-containing RNA population. This indicates an enrichment of these sequences within the cytoplasm. Moreover, no significant protection was afforded by a lactating mammary

Fig. 1 a, The comparative hybridization kinetics of (1) liver cytoplasmic poly(A)-containing RNA against its homologous cDNA preparation at RNA concentrations of 20  $\mu\text{g ml}^{-1}$  ( $\bullet$ ), 200  $\mu\text{g ml}^{-1}$  ( $\square$ ) and 1  $\text{mg ml}^{-1}$  ( $\blacksquare$ ), (2) liver nuclear poly(A)-containing RNA against its homologous cDNA preparation at RNA concentrations of 100  $\mu\text{g ml}^{-1}$  ( $\triangle$ ) and 1  $\text{mg ml}^{-1}$  ( $\blacktriangle$ ), and (3) the heterologous hybridization of cDNA prepared from mammary gland nuclear poly(A)-containing RNA against liver nuclear poly(A)-containing RNA at RNA concentrations of 200  $\mu\text{g ml}^{-1}$  ( $\circ$ ) and 1  $\text{mg ml}^{-1}$  ( $\bullet$ ). The dashed line represents the hybridization of mammary gland nuclear poly(A)-containing RNA against its homologous cDNA. b, cDNA synthesized from mammary gland nuclear poly(A)-containing RNA was fractionated into high- and low-frequency probes by limited hybridization to a  $R_0t$  value of 1.0 mol nucleotide per 1 s followed by separation of double- and single-stranded sequences on hydroxyapatite<sup>4</sup>. The high-frequency cDNA population was then hybridized to either the mammary gland nuclear poly(A)-containing RNA population at an RNA concentration of 100  $\mu\text{g ml}^{-1}$  ( $\triangle$ ), or the equivalent liver population at an RNA concentration of 1  $\text{mg ml}^{-1}$  ( $\circ$ ). Low-frequency cDNA probes were hybridized to mammary gland ( $\blacktriangle$ ) or liver nuclear poly(A)-containing RNA ( $\blacksquare$ ), both at an RNA concentration of 1  $\text{mg ml}^{-1}$ . The dashed line represents the hybridization of mammary gland nuclear poly(A)-containing RNA against its homologous RNA<sup>4</sup>.

Poly(A)-containing RNA was isolated from total nuclear or cytoplasmic RNA, and  $^3\text{H}$ -labelled cDNA synthesized from each population (specific activity  $1.45 \times 10^7$  c.p.m. per  $\mu\text{g}$ ) using avian myeloblastosis virus reverse transcriptase. Hybridizations were performed in RNA excess and the degree of hybridization determined using  $S_1$  nuclease digestion. Estimations of RNA complexity were based on the comparative hybridization kinetics of a rabbit globin mRNA standard after best line fit by computer and the appropriate adjustment of the observed  $R_{0.1/2}$  values (mol nucleotide per l s). Estimation of the number of sequences in each transition for the liver RNA populations was based on a number average molecular size of 1,590 and 1,390 nucleotides for the nuclear and post-nuclear populations, respectively, as determined by sucrose gradient centrifugation in the presence of formamide. Values in square brackets represent numbers previously calculated for the lactating mammary gland<sup>4</sup>. All procedures were as described previously<sup>4,5,7</sup>. Subsequent best line fits using fractionated cDNA probes in homologous or heterologous hybridizations have been assessed by eye (see Figs 1, 2).

gland cytoplasmic poly(A)-containing RNA population, thereby demonstrating the specificity of the cDNA probe.

The results reveal a remarkable degree of sequence homology within the nuclear poly(A)-containing RNA sequences isolated from two different tissues, one from a male and one from a female animal of the same species. Quantitative differences were also evident, but were restricted to the high-frequency poly(A)-containing RNA sequences. Thus, in common with studies on the distribution of globin<sup>11-15</sup> and ovalbumin<sup>16</sup> mRNA sequences, the RNA sequences found at high frequency in mammary gland tissue<sup>4,5,7</sup> were present at very low frequency in a nuclear poly(A)-containing RNA population and could not be detected in a cytoplasmic poly(A)-containing RNA population isolated from a different tissue within the same species<sup>6</sup>. The accumulation of these sequences seems to be regulated in a different manner from the complex low-frequency poly(A)-containing RNA sequences.

Our observations have a parallel. In sea urchins, post-transcriptional mechanisms seem to predominate, because transcribed single-copy nuclear sequences are common to embryo and adult tissues<sup>8</sup>, but cytoplasmic mRNA populations differ considerably<sup>9,17</sup>. We have investigated two tissues, one of which, the liver, contains a relatively heterogeneous cell population<sup>18</sup> compared with the mammary gland, which is predominantly epithelial<sup>19</sup>. This disparity in cell type presumably accounts for

the increased complexity of the liver cytoplasmic poly(A)-containing RNA population, thereby reflecting different functional requirements of different cell types even within the low-frequency populations. About 75% of the mammary gland low-frequency cytoplasmic poly(A)-containing RNA sequences are also present in the equivalent liver subcellular fraction (I.C.B. and R.K.C., unpublished). Some of these will direct the synthesis of the 'house-keeping' proteins, those proteins required by all cells<sup>9,20,21</sup>, others will represent cell-specific RNA sequences from cell types common to both tissues. The remainder, those not found in the liver, must represent a class of low-frequency poly(A)-containing RNA sequences peculiar to the mammary gland.

Overall, our studies support the concept that post-transcriptional mechanisms determine the accumulation of the low-frequency class of poly(A)-containing RNA sequences within the cytoplasm of guinea pig tissues. Thus although this population of sequences when located in the nucleus of two different tissues is very similar, examination of the relative distribution of these sequences within the cytoplasm reveals considerable tissue-specific differences. The precise nature of these post-transcriptional mechanisms has not been established, but probably involves correct processing of the primary RNA transcripts<sup>22-24</sup>, resulting ultimately in tissue- or cell-specific expression in the cytoplasm.

We thank Professor P. N. Campbell, Dr L. Hall and Dr M. S. Davies for helpful discussions, and the Wellcome Trust for supporting this work. Avian myeloblastosis reverse transcriptase was the gift of Drs J. Beard and J. Gruber.

Received 21 July, accepted 3 October 1980

**Fig. 2** A mammary gland cDNA probe representative of those sequences confined to the nucleus was prepared by hybridizing the cDNA preparation synthesized from nuclear poly(A)-containing RNA with a post-nuclear poly(A)-containing RNA population to a  $R_{0.1/2}$  value of 100 mol nucleotide per l s. Single-stranded cDNA (65% of starting material) was recovered by hydroxylapatite column chromatography<sup>4</sup>, then used as a source of mammary gland nucleus-specific cDNA. This was hybridized to poly(A)-containing RNA from the mammary gland cytoplasmic fraction (○), the liver nuclear (●) and liver cytoplasmic fraction (■), all at an RNA concentration of  $1 \text{ mg ml}^{-1}$ .

## The higher order structure of chicken erythrocyte chromosomes *in vivo*

J. P. Langmore\* & C. Schutt

MRC Laboratory of Molecular Biology, Hills Road, Cambridge CB2 2QH, UK

Recently eukaryotic chromosomes have been shown to consist of a repeating subunit, called the nucleosome<sup>1</sup>. Although electron microscopy, neutron scattering and X-ray diffraction have been used to determine the low resolution structure of the nucleosome, these techniques have yielded little information about the disposition of nucleosomes within chromosomes. Electron microscopy has produced many models for chromosome structure based on uniform fibres of 150–500 Å diameter or on globular 'superbeads'<sup>2–6</sup>. Unfortunately the models are based on microscope images that fail to reveal the strong structural periodicities shown by X-ray scattering to be characteristic of isolated chromatin in solution. Moreover it has not been demonstrated that the chromosomes of living cells are composed of such fibres. We have used low-angle X-ray scattering to investigate the organization of chromosomes *in vivo* and to account for the previously observed inconsistencies in many X-ray and electron microscope observations. We report here that chicken erythrocytes have a 400 Å periodicity due to a nuclear structure that is directly related to the 300 Å side-by-side packing of chromosome fibres revealed by electron microscopy of embedded cells, and that this periodicity can be preserved in isolated nuclei provided that the proper buffers are used.

Studies of concentrated isolated chromatin by X-ray and neutron scattering have shown dominant structural periodicities at about 110, 55, 38, 27 and 22 Å<sup>7–14</sup>. The intensities and exact positions of these bands depend on ionic composition of the solution and chromatin concentration. Significantly these low-angle studies have not revealed the 150–500 Å packing bands predicted by all the existing models for chromatin. However, the 110 Å band has been used as indirect evidence that helical 300 Å thick fibres exist<sup>13,14</sup>. Studies of dilute isolated chromatin have shown variable 400–460 Å, weak 200 Å, and weak variable 140 Å periodicities in one case<sup>15</sup>, and absent 400 Å, absent 200 Å, strong 110 Å, absent 55 Å, and strong 33 Å in another case<sup>14</sup>. Unfortunately, solution studies cannot be definitive because partial nuclease digestion and sub-physiological ionic strength are required for chromatin solubility. In fact, as the ionic strength is raised, increasingly compact higher order structures are formed<sup>16–18</sup>.

A typical diffraction pattern from living chicken erythrocytes is shown in Fig. 1a. A shoulder in the intensity is apparent at a spacing of ~400 Å. Patterns from rabbit enucleated erythrocytes do not give rise to this shoulder and possess only low-angle scattering from the concentrated intracellular haemoglobin (Fig. 1b). Buffer alone produced only uniform scattering of low intensity (Fig. 1c). By subtracting the measured intensities of nucleated from enucleated erythrocytes, we produced a difference curve (Fig. 2a) representing the structural differences (presumably nuclear) between these cells. A strong 400 Å peak is present in this curve.

The nuclear origin of the 400 Å peak is demonstrated by diffraction from chicken erythrocyte nuclei isolated by lysis of the cells with MLB buffer (see legend to Fig. 1) of near-

physiological ionic strength and containing magnesium (Figs 1f, 2b). The isolated nuclei also scatter at 200, 106, 60, 38 and 30 Å (Figs 1d, e, 2b, 3a). The nuclear spacings smaller than 400 Å were not obvious in the patterns from whole erythrocytes, due to the reduced contrast and increased background from the high internal concentration of haemoglobin. Diffraction patterns from live chicken and mouse lymphocytes, MOPC-21 and HeLa tissue culture cells, sea urchin, scallop and frog sperm cells, and from nuclei of all these cells clearly show the 106, 60, 38, 30 and 22 Å bands to be common to whole cells as well as their nuclei. Further discussion of these results will be published elsewhere.

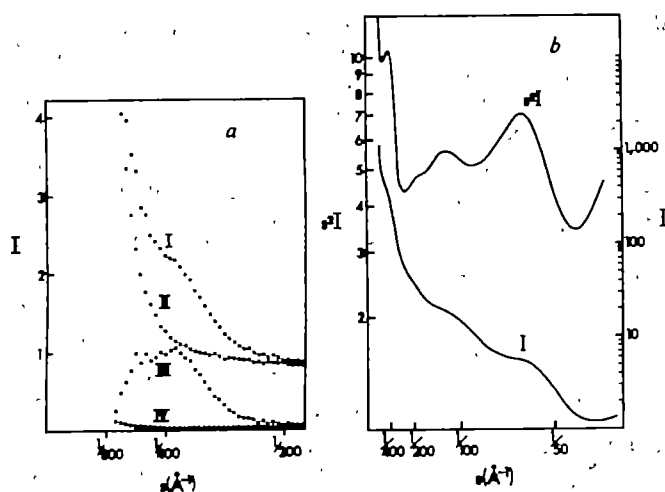

We are confident that the 400 Å band is of chromosomal origin because it is eliminated by nuclease treatment (Fig. 3a). Also thin sections of embedded erythrocytes reveal periodicities of comparable spacings only in the chromocentres (condensed regions of chromatin) and a lack of extraneous cytoplasmic and nuclear structures such as ribosomes, microtubules, mitochondria and nucleoli, which might in other cell types give rise to non-chromosomal low-angle bands. However, electron microscopy of chicken erythrocytes<sup>4</sup> and of isolated nuclei (unpublished results) indicate that the chromocentres have a granular internal structure with a periodicity of only 300 Å, apparently composed of square-packed thick fibres of ~300 Å diameter.

**Fig. 1** Low-angle X-ray diffraction patterns recorded on a Franks<sup>22</sup> camera with two 20-cm bent-glass mirrors and a 33.3-m specimen-to-film distance, mounted on a GX-13 rotating anode X-ray generator (Marconi-Elliott Avionics) producing 1.54 CuK $\alpha$  nickel-filtered radiation. The specimens were cooled to 5 °C and continuously translated over 2–3 cm during the X-ray exposure. The patterns were recorded on Ilford G film and uniformly developed. Aliquots of blood (1 ml, freshly collected with 10 unit ml<sup>-1</sup> heparin) were washed three times by centrifugation at 100g for 5 min in 10 ml of wash buffer (consisting of 130 mM NaCl, 5 mM KCl, 2 mM MgCl<sub>2</sub> and 10 mM HEPES, pH 7.3) and centrifuged into capillaries at 100g. X-ray exposure caused no noticeable haemolysis or uptake of trypan blue. Nuclei were prepared by lysis and resuspension of the pelleted cells three times for 3 min in 10 ml of MLB (consisting of 60 mM KCl, 15 mM NaCl, 15 mM HEPES, pH 7.3, 2 mM MgCl<sub>2</sub>, 0.1% Nonidet P-40 and 1  $\mu$ M fresh phenylmethylsulphonyl fluoride (PMSF)) and centrifuged into capillaries at 1,000g. SDS-polyacrylamide gel electrophoresis of nuclei after X-ray exposure showed no evidence of histone proteolysis. *a*, 4.2 h exposure from living chicken erythrocytes. *b*, 4.5 h exposure from living rabbit erythrocytes. *c*, 16.5 h exposure from wash buffer in capillary. *d*, Pattern from isolated chicken erythrocyte nuclei reproduced to illustrate the 60 Å and 38 Å bands. *e*, Pattern from isolated chicken erythrocytes reproduced to illustrate the 106 Å band. *f*, Pattern from isolated chicken erythrocytes (recorded at 44 cm specimen-to-film distance using Kodak Industrex AA film) reproduced to illustrate the 400 Å band. Length of the bar in *a* represents 1/50 Å<sup>-1</sup> in *a–e*. Bar in *f* represents 1/200 Å<sup>-1</sup> in *f*. *a–c* have been identically reproduced. The 400 Å shoulder is almost as visible by eye as the 106 and 60 Å features. The 200 Å shoulder is very weak and very difficult to visualize in photographic prints. The entire series of reflections from nuclei was consistently observed in more than 20 preparations using various conditions, including pH in the range 6–8, in the presence of 15 mM 2-mercaptoethanol, and in the presence of 1 mM CaCl<sub>2</sub>. Very small amounts of proteolysis eliminate the 400 Å shoulder.

\* Present address: Division of Biological Sciences and Biophysics Research Division, The University of Michigan, Ann Arbor, Michigan 48109.

**Fig. 2** Quantitative analysis of erythrocyte diffraction patterns. *a*, Measured chicken erythrocyte intensities (from the pattern shown in Fig. 1a); curve I, measured rabbit erythrocyte intensities (from the pattern shown in Fig. 1b); curve II, the difference between chicken and rabbit erythrocyte intensities; curve III, measured camera and solvent background (from the pattern shown in Fig. 1c) normalized to 4.3 h exposure time; curve IV, the mode of the difference curve is at  $\sim 380$  Å, and the mean is at  $\sim 410$  Å. *b*, The measured intensities from chicken erythrocyte nuclei in MLB showing a diffraction pattern on a steep background. I, average scattered intensity and  $s$ ,  $2 \sin(\theta/2)/\lambda$  where  $\theta$  is the scattering angle and  $\lambda$  the wavelength. By multiplying the recorded intensities by  $s^2$  we can correct for the random orientation of the fibres with respect to the X-ray beam, and for the high specimen background that seems to decrease as  $1/s^2$ , thereby calculating the true relative strengths (power) of the structural periodicities in the specimen. The chicken intensities are normalized to the rabbit intensities at  $0.005$ – $0.006$  Å $^{-1}$  using a multiplicative factor of 1.3 to correct for the slightly different cell concentrations in the two samples. In this angular range less than 10% of the scattering originates from the nuclei, as estimated by measurements of the steeply falling scattering from isolated nuclei. Two-dimensional densitometry was carried out using a 'Photoscan' (Optronics) controlled by an interactive computer program. A 50- $\mu$ m step size (equivalent to steps of  $s = 0.000098$  Å $^{-1}$ ) was used. Specular optical densities in the range 0–2 were measured and related to X-ray intensities using data applicable to Ilford G film<sup>22</sup>. The intensities at the centre of each pattern were displayed to allow the operator to determine the centre of scattering and to exclude unwanted areas of film from analysis. The scattering centre was established by briefly exposing the film to the direct X-ray beam, by moving the beam stop to one side after recording the diffraction pattern. The accuracy of this centre was checked by comparing the distribution of intensity with radius from above and below, and from left and right, of the centre. The centre was refined until the centre of analysis was to within one half raster unit (25  $\mu$ m) of the scattering centre. To exclude unnecessary camera background and the beam stop shadow on each pattern, a rectangular area covering these unwanted areas was excluded from analysis. Non-excluded data points in the two horizontal quadrants were averaged within annuli of different radii to give the average intensity distribution as a function of radius. The existence of the 400 Å band was also confirmed by the visual appearance of a 400 Å shoulder on all three films in the film pack and by the presence of the 400 Å shoulder in one-dimensional densitometer measurements.

To establish the relevance of the X-ray spacing *in vivo* and *in vitro* to the microscopical structures, we recorded diffraction patterns during the different preparative steps for microscopy. Although fixation and uranyl acetate staining caused a slight expansion of the structure, ethanol dehydration and embedding in epoxy caused broadening and progressive shrinking of the spacing to 310 Å (Fig. 3b). This indicates that the apparent side-by-side partially ordered packing of 300 Å fibres observed by Davies<sup>4</sup> and us in thin sections is probably directly correlated to the more orderly packing of 400 Å fibres *in vivo*. In addition, dehydration distorts the internal structure of the fibres as shown by loss of the 106 and 60 Å bands and appearance of a broad 70 Å band (Fig. 3a), consistent with earlier studies of dehydration<sup>10,12</sup>.

When chromocentres are dispersed by replacing the MgCl<sub>2</sub> (2 mM) of MLB with 2 mM EDTA a homogeneous distribution of thick fibres within the nuclei is seen by electron microscopy and the 400 Å band disappears—all the other reflections are preserved (manuscript in preparation). This substantiates our hypothesis that the 400 Å spacing is from the packing of

nucleofibres and that the 200, 106, 60, 38, 30 and 22 Å periodicities reflect the internal structure of the fibres.

Do our results resolve any long-standing problems in the interpretation of chromatin X-ray patterns? Our consistent observation of a 106 Å band in each cell type and nucleus examined establishes this periodicity as characteristic of intact chromosomes. Previous investigators have been uncertain that this was an invariant feature of chromatin, especially in nuclei<sup>7,8,10,19,20</sup>. We have consistently found the 400 Å band present in chicken erythrocytes and erythrocyte nuclei and absent when the fibres are dispersed, which shows that this band is due only to fibre packing and not to periodicities within the fibres themselves. This contradicts Bram and collaborators who conclude that there is a concentration-independent 300–450 Å periodicity in isolated chromatin fibres<sup>15,20</sup>. Furthermore these investigators were unable to find the characteristic 106 Å band in isolated chromatin or nuclei, perhaps due to their use of very low ionic strength buffers.

The reflections seen in whole cells and isolated nuclei have been difficult to visualize due to their diffuse nature and steep background scattering. The lack of sharpness of the bands was not a preparation artefact, but was due to apparent disorder in chromosome structure. The width of the 400 Å band is probably due to heterogeneity or disorder in the packing of the nucleofibres or because the fibres are organized in small domains. Certainly chromosome fibres do not pack with the high degree of long-range crystalline order found in skeletal muscle or collagen. However, even after embedding in plastic, which causes considerable broadening of the packing band, nucleofibres show a degree of packing order easily recognized in electron micrographs. The diffuse nature of the 200, 106, 60, 38, 30 and 22 Å peaks is not inconsistent with a highly regular nucleofibre internal structure, because in the absence of excellent packing order there are several factors that result in broad bands, including inherent diffuseness of the molecular Fourier transform as in the case of the Bessel functions that describe diffraction from helical fibres, and also random fibre orientation, which leads to overlap of bands at similar angles. In fact, diffraction from the nucleofibre internal structure is no more diffuse than diffraction from randomly oriented double-stranded DNA in solution or in chromatin<sup>4,21</sup>. The presence of a

**Fig. 3** Effects of dehydration and nuclease digestion on X-ray scattering. *a*, Chicken erythrocyte nuclei in MLB (curve I), after embedding in Araldite (curve II), and after nuclease digestion (curve III). For embedding, nuclei were fixed in 1% glutaraldehyde for 10 min at 0 °C, washed in H<sub>2</sub>O, stained in 1% UO<sub>2</sub> for 10 min, dehydrated with increasing concentrations of ethanol, propylene oxide and then Araldite, followed by polymerization at 60 °C for 2 d. Nuclei at a concentration of about 100 A<sub>260</sub> per ml were digested at 37 °C for 15 min with 5,000 units of micrococcal nuclease and 300 units of DNase I. *b*, Diffraction patterns from chicken erythrocyte nuclei: Curve I, *in vivo* from Fig. 2a; curve II, isolated nuclei in MLB; curve III, isolated nuclei in water after fixation and staining as above; curve IV, fixed and stained nuclei in ethanol; curve V, fixed and stained nuclei embedded in Araldite. All curves are arbitrarily positioned on the ordinate in order to minimize overlap, and are therefore not meant to portray the relative intensities but to show the positions of the maximum and minimum in the  $s^2I$  function.

large amount of background scattering in the patterns from living cells and nuclei is not surprising because the fibres are not homogeneously distributed in the sample, but are concentrated in small chromocentres that strongly scatter X rays much as they do visible light. Centrifugation of the nuclei into a transparent pellet eliminates most of this background.

Although the local packing of nucleosomes within chromosomes is conserved among chicken erythrocytes, mouse lymphocytes, HeLa and MOPC-21 cells and several chromatin-containing sperm (as revealed by constancy of the 106, 60, 38, 30 and 22 Å spacings) higher order structure seems to be cell

dependent. For example, lymphocytes have a 330 Å rather than 400 Å periodicity, whereas sperm seem to lack a higher order spacing in the 300–500 Å range (unpublished data). These results suggest that variations in chromosome folding may involve only subtle changes in the local packing of nucleosomes.

## Solid-like behaviour of unsheared sickle haemoglobin gels and the effects of shear

Robin W. Briehl

Departments of Physiology and Biochemistry, Albert Einstein College of Medicine, Bronx, New York 10461

**Pathogenesis in sickle cell disease depends on the polymerization of deoxyhaemoglobin S into long fibres followed by 'gel' formation. The 'gelation' renders the affected erythrocytes less deformable than normal so that they obstruct the microvasculature and the 'gelation' process has been one of the targets for the development of therapeutic treatments of sickle cell disease. 'Gelation', however, acts through the rheological properties it induces and rheological abnormalities are therefore the immediate bases of pathogenesis. Although there has been very little study of the rheology of haemoglobin S haemolysates, the 'gels' are generally considered to be highly viscous and thixotropic on the basis of gross observation. Limited and generally qualitative observations show that high viscosity depends on deoxygenation<sup>1,2</sup> and exhibits hysteresis in gelling/ungelling cycles<sup>3</sup>; also that shearing accelerates gelation<sup>3,4</sup> and can induce formation of fibre aggregates and crystals in suspension which, in contrast to the 'gel', are fluid<sup>5</sup>. Using transient and steady state methods it is shown here that unsheared sickle deoxyhaemoglobin preparations are solid-like, consistent with a gel-like nature, whereas shearing converts them to thixotropic viscous systems. These results underline the marked variation and thixotropy the system can undergo and may be relevant to the pathogenesis, clinical course and therapy of sickle cell disease.**

Haemoglobin S solutions were prepared from homozygous haemolysates by chromatography on Whatman DE 52 (ref. 6), dialysis into 0.1 M potassium phosphate, pH 7.0, and deoxygenation at 0°C under nitrogen only. These were transferred cold into a thermostatted Wells-Brookfield RVT Rheolog cone-plate microviscometer in a glove box kept free of oxygen by recirculation of 3% hydrogen in nitrogen over a palladium catalyst. The absence of oxygen was confirmed by (1) a methylene blue indicator, (2) polarographic analysis with a Clark electrode and (3) spectral examination of aliquots of haemoglobin removed from the viscometer. The viscometer cone angle ( $\alpha$ ) was 1.565° so that the speed range from 0.5 to 100 r.p.m. corresponded to shear rates from 1.92 to 384 per s. At 10 r.p.m. the relation between viscosity in centipoise,  $\eta_{cP}$ , and stress ( $\sigma$ ) in dyn cm<sup>-2</sup> is  $\eta_{cP} = 2.61\sigma$ . The cone radius ( $R$ ) was 2.4 cm. The

spring constant ( $k$ ) for the coupling between the synchronous motor and the cone was 1,760 dyn cm. Shearing stress was observed on a digital readout and a continuous record of it and temperature, measured with a thermistor attached to the viscometer cup, was obtained with a Hewlett-Packard 7754A oscillographic recorder. Full scale stress was 245 dyn cm<sup>-2</sup>, occurring at an angular lag of the cone behind the motor of 231°.

After the haemoglobin was introduced into the viscometer, shearing was begun at 10 r.p.m. and gelation was induced by a step increase in temperature. The half time of the step was about 2 s and, the last stages of warming being slower, final temperature was attained within 0.2°C in about 2 min. (Confirmation that sample temperature increased at the same rate as that of the cup was obtained by observing the viscosity of a mixture of glycerol, 75% by weight in water, during a step increase in temperature.) Deoxyhaemoglobin S viscosity remained constant during the delay period incubation<sup>7,8</sup>, after which it began to increase. For preparation of unsheared gels, the viscometer was turned off when viscosity reached 13 cP, about 4 times the solution value, and annealing under neither stress nor shear was then permitted for 30 min.

After each experimental procedure, the gel was melted by cooling to 1–2°C for 1 h, the first 10 min in the absence of shear, followed by 40 min at 100 r.p.m. and then 10 min at 10 r.p.m. before the next induction of gelation by warming. Supportive evidence that this melting procedure fully reversed the gelation is provided by (1) the return of viscosity to the previous cold level, (2) constancy of viscosity towards the end of the 40 min period, (3) the reproducibility of the delay time and viscosity progress curve in the next induction of gelation and (4), the lack of change in observed properties of the gel when an experiment was repeated.

In Fig. 1a a gel incubated and annealed at 20°C was subject to slowly increasing stress when the viscometer motor was turned on at 0.5 r.p.m. After the linear increase in stress, upon attaining full scale, the motor was stopped. Stress did not decay. In experiments of up to 10 days, no decay was seen (to within one part in 250). Employing the equation for viscous decay of stress in a cone-plate geometry  $\sigma = \sigma_0 \exp(-3kat/2\pi R^3\eta)$  where  $t$  is time and  $\eta$  is viscosity (in poise), viscosity must be higher than  $3 \times 10^{10}$  cP. This very large value justifies designating the gel as solid-like rather than viscous. When, in some experiments, stress was relieved by rewinding the motor manually, re-application of stress produced identical results, confirming that the solid-like nature of the gel was not damaged.

During application of stress, the rate of increase was, within the limits of measurement (~1%), the same as that obtained (the

maximum rate) when similar stressing was carried out with the cone held fixed by water frozen in the viscometer. Therefore, the cone remained essentially immobile and the gel suffered little or no deformation; that is, because the rate of stress increase reflects deformation of the coupling spring, the rate of rotation of the cone, here essentially zero, can be calculated. A deviation of 1% in the rate of increase of stress from the maximum rate would correspond to an elastic shear modulus of  $165 \text{ dyn cm}^{-2}$ , hence the modulus for the gel was equal to or greater than this.

At the three lower temperatures in Fig. 1a the gels showed yield values and peak stresses, both decreasing with decreasing temperature. Figure 1b shows a similar series of experiments, differing only in the time at which temperature was adjusted to the final level; the essential results are the same. Therefore, solid-like strength of gels, manifested in a yield stress, depends

**Fig. 1** *a*, Unsheared gels hold stress up to a yield stress, which depends on temperature. Five experiments were done sequentially on a sample 13.5 mM in haem at different temperatures. The ordinates represent shearing stress ( $\sigma$ ) with a scale factor difference of 10 between left and right hand ordinates; the changes occur at the diagonal lines, at which time there is also a break in the time scale. The zero point on the ordinate scale applies to the experiment at  $12.5^\circ\text{C}$ ; the other curves are displaced upwards for clarity, with each baseline indicated. In each experiment a temperature jump (at the arrow) from  $1^\circ\text{C}$  to  $20^\circ\text{C}$  under shear at 10 r.p.m. resulted in a fall in viscosity (associated with warming). At the end of the delay period, stress and viscosity ( $\eta_{sp}/c = 2.61\sigma$ ) rose until shearing was stopped. The temperature was then decreased in a few minutes from  $20^\circ\text{C}$  to that of the subsequent stressing experiment and the gel was annealed for 30 min under no stress or shear. Stress was then applied by running the synchronous motor at 0.5 r.p.m., stopping it only if stress reached full scale (as in the experiments at  $20.0^\circ\text{C}$  and  $18.0^\circ\text{C}$ ). At  $20.0^\circ\text{C}$  and  $18.0^\circ\text{C}$  the curves were superimposable and both gels held stress at full scale with no decay. At the three lower temperatures the stresses at which the gels broke (as defined by a deviation of  $5 \text{ dyne cm}^{-2}$  from the line of maximal rate of stress increase) are indicated (X); these curves also showed maxima in stress as shearing at 0.5 r.p.m. was continued. *b*, In these experiments (on a different sample) gelation was induced by a temperature jump to a level which then remained unchanged through incubation, annealing and stressing. The delay times associated with the serially decreasing temperatures were 5.7, 11.0, 18.0 and 34.6 min. The viscosity progress curves differed and were more rapid at higher temperatures. The time scale is broken during incubation to make the starts of the 30 min annealing periods coincident. At  $19.9^\circ$  rotating the motor at 0.5 r.p.m. induced stress increase at the maximal rate. After the motor was stopped there was a very slow decay of stress. At  $17.3^\circ\text{C}$  a yield stress was attained just before full scale stress was attained; decay at 0 r.p.m. thereafter was more marked. At the two lower temperatures, successively smaller yield stresses and peak stresses occurred.

on temperature in the manner which would be expected from the endothermic nature of gelation<sup>1,9</sup>. The energy of activation calculated from the delay times in Fig. 1b is  $50 \text{ kcal mol}^{-1}$ , neglecting any temperature-dependent effect of shearing.

Figure 2 defines a yield temperature and, reciprocal to the temperature dependence of yield stress in Fig. 1, shows that it depends on stress.

**Fig. 2** Stress dependence of yield temperature. *a*, in separate experiments on a 14.0 mM sample, gels were formed and then annealed at  $20^\circ$  for 30 min as in Fig. 1a. Each gel was then stressed ( $\uparrow$ ) by rotation of the motor at 0.5 r.p.m. until the desired stress was reached ( $\downarrow$ ). At this stress, which did not decay, the gel was cooled slowly, beginning at time 0, until a rapid relaxation occurred, indicative of breaking of the gel. The yield temperatures thus defined, shown on each curve, decrease with decreasing applied stress. The time scale is broken at the diagonal lines. The temperature decrease shown is a superposition of the experiments and, because there were small variations in the rate of cooling, the times of breaking shown are approximate (within 1 min). The yield temperatures at the two higher stresses are each the average of two experiments, differing by  $0.2^\circ\text{C}$  or less. *b*, The dependence of yield temperature on stress (plotted logarithmically) is shown over a large, 40-fold, range of stress in a series of experiments on another sample, 13.7 mM in haem.

**Fig. 3** Solid-like behaviour of gels during the growth stage of gelation. Nine experiments on a 13.4 mM sample at  $26^\circ\text{C}$  are shown. The delay times (defined here as the time required for viscosity to reach 13 cP) were all between 3.62 and 3.82 min. Shearing was carried out at 10 r.p.m. until a desired viscosity, from 13 cP in the first experiment in *a* to 320 cP in the last in *c*, was attained. In *a* full and rapid relaxation to zero stress occurred in the first experiment. In the second, spindle inertia induced a transient oscillation (off scale, below 0) in stress with a final constant value of  $-1.5 \text{ dyn cm}^{-2}$ . In the third experiment the motor was stopped when viscosity was 56 cP. Full relaxation did not occur, as was also the case in all experiments in *b* and *c*. These gels held stresses without long term decay and were therefore solid-like rather than viscous. The rapid partial relaxation occurring immediately after peak viscosity is in whole or part an artefact associated with inertial properties of the cone spindle; it continued to rotate briefly after the motor had stopped and thus the transient rapid decay reflects this as well as (or instead of) any inability of the gel to hold the maximum stress attained. Thus, the final asymptotic stress is a lower limit on the stress the gel might hold.

**Fig. 4** Well sheared gels are viscous. *a* shows, as in Fig. 1, the stressing after annealing of a gel of 13.5 mM deoxyhaemoglobin S at 20°C; full scale stress was held. Then the gel was sheared at 10 r.p.m. for 10 s (during which stress was off scale), resulting in partial relaxation to an asymptotic stress of 64 dyn cm<sup>-2</sup>, indicating viscoplastic behaviour. Fifteen minutes later (during 8 of which the gel was sheared at 10 r.p.m.) the gel showed a time-dependent thixotropic decay in viscosity under continuing shear at 10 r.p.m. After prolonged shear for 120 min at 10 r.p.m., the viscosity reached a final constant value, shown at the start of *b*. Stopping the viscometer then resulted in rapid relaxation to zero stress. Under stressing at 0.5 r.p.m. the gel failed to hold any significant stress, a constant level reflecting viscosity only being attained. On stopping the motor, relaxation was again complete. After 30 min of annealing under no shear, the final part of *b* shows that rotation of the motor at 0.5 r.p.m. resulted in a peak in stress higher than that in the previous stressing, followed by a fall to a level dictated by viscosity, also higher than previously, indicating that some reannealing occurred.

In Fig. 3 shearing was continued after the delay period into the stage of fibre growth<sup>4</sup> to different levels of viscosity. When shearing was stopped after viscosity had reached about 50 cP or more little or no relaxation occurred and the gels held large stresses, showing that the rheological behaviour was essentially solid-like rather than viscous.

By contrast, Fig. 4 shows that well sheared gels held no measurable stresses and were therefore purely viscous. Also, (apparent) viscosity decreased with time under shear and, after a period of no shear, reannealing occurred, demonstrating the presence of viscous thixotropy. Also in Fig. 4, gels subject to brief shear were viscoplastic, manifesting viscous decay to a non-zero asymptotic stress.

These results show that unsheared gels of haemoglobin S are solid-like, well sheared gels are purely viscous, and intermediate, viscoplastic conditions also occur. Also, thixotropy exists in the sense of conversion between solid-like and viscous behaviour as well as in the more usual sense of shear and time dependence of viscosity.

This observation of solid-like behaviour with a plastic yield stress provides justification for the designation 'gel', applied previously even though the system was generally described as 'highly viscous'.

The existence of solid-like properties may have a bearing on pathogenesis in sickle cell disease. An erythrocyte containing a purely viscous interior would deform to an extent dependent on the time integral of stress and thus might eventually pass the microvasculature. On the other hand, a solid-like erythrocyte could not deform unless a critical yield stress were attained. Because shearing history governs the solid-like or viscous nature of the gel, it may also govern the pathogenic potential of each erythrocyte. Whether shear is a favourable or unfavourable factor, however, depends on its effect on gel rheology and also on the fact that it accelerates the delay stage of gelation<sup>3,4</sup>.

Generally, these observations show that gel rheology is highly modifiable even in the absence of alteration of the thermodynamics and kinetics of gelation, and thus that pathogenesis in this highly variable disease may be influenced by the highly variable rheology of gels.

## A variant surface glycoprotein of *Trypanosoma brucei* synthesized with a C-terminal hydrophobic 'tail' absent from purified glycoprotein

J. C. Boothroyd\*, G. A. M. Cross\*, J. H. J. Hoelmakers† & P. Borst†

† Universiteit van Amsterdam, Afdeling Medische Enzymologie, Laboratorium voor Biochemie, Jan Swammerdam Instituut, PO Box 60.000, 1005 GA, Amsterdam, The Netherlands

Sequential expression of variant surface glycoproteins (VSGs) enables the parasitic protozoan *Trypanosoma brucei* to evade the immune response of its mammalian hosts<sup>1,2</sup>. Studies of several VSGs, which have been isolated as soluble molecules following disruption of cells in the absence of detergent, have indicated extensive amino acid diversity<sup>3-5</sup> and the absence of a hydrophobic segment which might serve to anchor the carboxy terminus to the membrane<sup>6</sup>. The carboxy-terminal tryptic peptides of six VSGs have recently been characterized and shown to be glycosylated<sup>6</sup>. Three of these VSGs terminated with a glycosylated aspartate or asparagine residue (Asx), suggesting that the VSG was cleaved following synthesis and glycosylation and before characterization. We present here nucleotide sequence data which suggest that the primary translation product of one VSG gene contains a hydrophobic tail at the carboxy terminus which is not found on the isolated, mature glycoprotein<sup>6</sup>. The data also predict that the glycosylated residue is aspartic acid rather than the anticipated asparagine.

We have recently reported the synthesis and molecular cloning into the plasmid pBR322 of complementary DNA (cDNA) molecules corresponding to the VSGs of four variants of a single clone of *T. brucei*<sup>7</sup>. As extensive amino acid sequence data on one of these VSGs (VSG 117) already existed (G. Allen, personal communication), we have selected the corresponding recombinants (T-cV117·1-8) for further study. As purified VSG 117 terminates with a glycosylated Asx<sup>6</sup>, suggesting post-glycosylation proteolytic cleavage of a VSG precursor, we decided first to determine the nucleotide sequence corresponding to the 3' end of the mRNA, coding for the carboxy terminus of the protein.

A physical map of the cDNA insert which extended furthest in the 3' direction (T-cV117·8) and the protein region it covers is given in Fig. 1. Also shown are the regions where useful nucleotide sequence information was obtained. Figure 2 presents a representative sequencing gel corresponding to the carboxy-terminal portion of the protein. The complete nucleotide sequence of this region and the implied amino acid sequence are

**Fig. 1** Physical map of T-cV117.8 showing restriction endonuclease cutting sites. Distances are in base pairs from the end of the insert nearest the *EcoRI* site of pBR322. These data were obtained by standard mapping procedures and subsequently confirmed by the DNA sequence. Beneath the map are shown the region of the insert which codes for the putative primary translation product and the carboxy terminus of the mature VSG (V). Below this are shown the sites which were [ $5'$ - $^{32}$ P]-end-labelled (●) and the regions where useful sequence information was obtained (→).

given in Fig. 3. The fact that there is neither a poly(A) stretch before the dC tail in Fig. 3 nor the sequence (AATAAA) usually found about 25 nucleotides upstream of the site of poly(A) addition<sup>8</sup> suggests that T-cV117.8 does not extend to the 3' end of the VSG 117 mRNA. This may be an artefact of the process by which these recombinants were constructed or selected<sup>7</sup>. The inferred amino acid sequence shown in Fig. 3 is in complete

**Fig. 3** Summary of nucleotide and protein sequence data. The nucleotide sequence of the coding strand between positions 445 and 1 (see Fig. 1) is given together with the implied amino acid sequence. Only one reading frame is open. The carboxy-terminal residue of the mature, isolated glycoprotein is underlined (see text). Glycosylated residues are marked with asterisks. (C)<sub>20</sub> indicates the dC-tail used to anneal the cDNA insert to the dG-tailed plasmid.

**Fig. 2** Autoradiograph of a representative sequencing gel corresponding to the carboxy terminus of VSG 117. A *HpaII* fragment of DNA from T-cV117.8 was [ $5'$ - $^{32}$ P]-end-labelled with polynucleotide kinase, recut with *TaqI* and purified on a 7% polyacrylamide gel essentially as described<sup>14</sup> except that the eluted fragment was further purified by binding to a 1-ml column of diethylaminoethyl-cellulose followed by elution in 0.5 M NaCl. Base-specific modifications and cleavage were as described<sup>14</sup>, with minor alterations as recently recommended by the authors (A. Maxam and W. Gilbert, personal communication). Analysis was on a thin (0.4-mm) 8% polyacrylamide gel in 7 M urea run at high voltage (1.6–2.0 kV) to reduce secondary structure effects<sup>15</sup>. Aliquots of each sample were loaded on to different tracks of the same gel at 0 (a) and 120 min (b), the gel being run for a total of 270 min. After cooling, the gel was fixed by immersing in 10% (v/v) acetic acid for 20 min, dried under vacuum with heat and autoradiographed at  $-70^{\circ}\text{C}$  in a Kodak cassette containing a Dupont Cronex Xtra-life intensifying screen. The nucleotide sequence corresponding to the C-terminal region of the protein is given to one side. This sequence is of the noncoding strand, the nucleotides being numbered as in Fig. 1.

agreement with independently derived data from the purified glycoprotein (ref. 6 and G. Allen, personal communication) except that protein sequencing indicated the carboxy terminus to be exclusively glycosylated Asx at position 154, whereas the nucleotide sequence shows 23 sense codons beyond this position before a stop codon is reached. It seems, therefore, that at some time after translation of the polypeptide and before characterization of the VSG, a highly specific proteolytic cleavage has occurred 23 amino acids in from the carboxy terminus.

Although we have not directly examined the carboxy-terminal sequence of the primary mRNA translation product, it is a reasonable assumption that it contains the extension predicted by the DNA sequence. This would be consistent with our previous observation<sup>7</sup> that 117 VSG mRNA translated *in vitro* yields a polypeptide which seems to be slightly larger on SDS-polyacrylamide gels than mature VSG isolated from trypanosomes, despite glycosylation of the latter which should increase its apparent molecular weight. The amino acid sequence towards the end of the predicted extension is extremely hydrophobic. We have been unable to define the role of the hydrophobic extension and the time at which it is cleaved. The fact that all six VSGs studied terminate with a glycosylated amino acid<sup>6</sup> suggests cleavage may be a specific event common to VSG processing in *T. brucei*.

Hydrophobic carboxy termini have been reported in surface proteins of influenza virus<sup>9</sup> and *Bacillus stearothermophilus*<sup>10</sup> and may generally serve to anchor membrane-bound cell-surface proteins<sup>11</sup>. Observations that carboxy-terminal glycopeptides of trypanosome VSGs carry an immunologically cross-reacting group<sup>6</sup>, which on living cells is not accessible to antibody<sup>12</sup>, are consistent with the carboxy terminus being in close proximity to the surface membrane. If present in the VSG molecules forming the surface coat of living trypanosomes, the hydrophobic extension could serve a membrane-binding function. However, no precedent exists for the rapid and specific cleavage which would be required to explain the observation that mature VSG is released on cell disruption, even when several inhibitors of proteolysis are present (G.A.M.C., unpublished observations). The existence of such a mechanism for specific cleavage and release of VSG from the cell surface suggests a role in antigenic variation, possibly in allowing

shedding of VSG complexed with antibody. Clarification of whether the hydrophobic extension is present on VSG at the cell surface must await the results of further experiments. Alternatively, the hydrophobic extension could act as a signal sequence during processing and secretion of VSG and could have been removed before arrival at the cell surface (in a manner analogous to amino-terminal leader sequences<sup>11</sup>). Comparison of the mature VSG amino terminus with the sequence inferred from the cDNA corresponding to the 5' end of the mRNA, however, indicates the presence of an amino-terminal extension similar to the signal sequences found on almost all secreted proteins<sup>11</sup> (J.C.B. and G. Allen, unpublished results).

Glycosylation of VSG 117 has been shown to occur at positions 304 and 154 (Fig. 3; ref. 6 and G. Allen, personal communication). The tripeptide Asn-Ser-Thr found at the first site (position 304) conforms to the general sequence Asn-Xxx-Ser/Thr thought to be a requirement for glycosylation at asparagine residues<sup>13</sup>. The other site, however, does not. Instead, the cDNA predicts the tripeptide sequence Asp-Ser-Ser, suggesting attachment of the carbohydrate moiety to

aspartate. To dismiss the possibility that this result was an artefact of the cDNA cloning procedure, a recombinant plasmid containing a genomic copy of the VSG 117 gene was analysed for the presence of the *Hinf*I cleavage site which is strictly dependent on the critical Asp codon (*GATTC*, positions 155–151, Fig. 3). The site was indeed present as defined by single and double digests with *Hinf*I and *Pst*I (J.C.B., unpublished results). It seems certain, therefore, that the primary translation product, at least, has Asp at position 154. We are now investigating whether the Asp is converted to Asn before glycosylation or is instead involved in a novel linkage to the carbohydrate. Similar analyses of cDNAs for other VSGs (now underway) should indicate whether the hydrophobic extension and glycosylated aspartic acid are universal features of the surface glycoproteins of *T. brucei*.

We thank C. A. Paynter for technical assistance, K. M. O'Hare and A. J. Newman for helpful advice and suggestions, G. Allen and A. A. Holder for communicating results before publication and critical reading of the manuscript, and A. C. C. Frasch, A. Bernards, C. Weissmann and M. Winther for supplying recombinant clones of VSG 117.

## BOOK REVIEWS

# Science East and West: reflections of Peter Kapitza

Nevill Mott

PETER Leonidovich Kapitza was born on July 9, 1894, and began his scientific work in the Polytechnic Institute of St Petersburg, from which he graduated in 1918. In 1921 he was sent by the Soviet authorities to work under Lord Rutherford in Cambridge, where he stayed until 1934, the Royal Society Mond Laboratory being built especially for his work on the development and effects of high magnetic fields and low temperatures. During this time he retained his Soviet citizenship, returning to Russia from time to time and telling his friends that he thought he was the only man of his country with a passport endorsed for unlimited journeys. However, in 1934, while attending a conference in Leningrad to celebrate the one-hundredth anniversary of the birth of Mendeleev, he was told that he could not return to Britain, and would have to continue his work in the Soviet Union. I was at the same conference, and remember the impression that Kapitza's Rover car, driven from Bergen round the gulf of Finland, made among the few official cars in the streets of Leningrad. In Russia he continued work in low-temperature physics, for which he was awarded a Nobel prize in 1978; after the War he was accused of giving wrong advice about oxygen production and was excluded from his laboratory for several years; rehabilitated, he turned to plasma physics (not nuclear energy as is sometimes thought), and in the past few years has been able to travel abroad.

This book, translated from the Russian, contains a collection of articles and addresses delivered by Kapitza during the past 50 years. Many have appeared elsewhere, for instance "Recollections of Lord Rutherford" and a biographical memoir of L.D. Landau published by the Royal Society, of which Kapitza is a Fellow. His reverence for and gratitude to Rutherford are well known; he writes:

... in the year that Rutherford died there disappeared forever the happy days of free scientific work which gave us such delight in our youth. Science has lost her freedom. Science has become a productive force. ... rich but enslaved, part of her veiled in secrecy.

Sir Nevill Mott is Emeritus Professor of Physics at Cambridge University; he knew Kapitza well between 1930 and 1934.

*Experiment, Theory, Practice: Articles and Addresses of P.L. Kapitza.* Boston Studies in the Philosophy of Science, Vol.46. Pp.429. (Reidel: 1980.) Hardback Dfl.90, \$47.35; paperback Dfl.28, \$14.75.

Peter Kapitza, July 1973

He writes, too, a moving appreciation of Paul Langevin, and of other figures from the past. From the past few years, when he could travel, come addresses to international bodies, such as one on the impact of modern scientific ideas on society to the Unesco symposium on the centenary of Albert Einstein. A few sentences will reflect his views about the way society is going in the developed countries of East and West alike.

The state compels a person to abide by its laws, and society compels him to live in accordance with his traditions. After a certain degree of well-being has been reached people begin to lose their liberty as their prosperity increases, and already the freedom of the individual in the developed countries is extremely limited. Modern society strives to organise people's lives in such a way that they will have an impression of freedom despite their lack of it. This is achieved by means of propa-

ganda and by turning people's interest towards sport, sex and entertainment so as to distract them from reality. Such were the principles on which society was organised in Aldous Huxley's *Brave New World*.

Kapitza seems to feel that it is not so very different in East and West. And in view of this, perhaps the most interesting parts of the book for the Western reader are his addresses to the Presidium of the Academy of Sciences of the USSR, for instance one in 1964, "The Effectiveness of Scientific Work". Here perhaps East and West do not appear so equal. He writes, in criticizing the situation in his own country:

An important factor in morale is to take part in scientific life abroad — at conferences and similar gatherings. As yet we take little part in them. Our delegates are still only one quarter or one fifth as many as those of the USA or other countries [are they now as many?] and often the delegates are selected by bureaucratic methods. . .

And in the same article, he writes that now nearly all those who should be leaders of science spend their time on committees, how every rouble must be accounted for even though money for research is not lacking. A director

cannot dismiss anyone, nor can he provide any incentive. The fettering of the Director, his restricted role in this important matter, is one of the reasons for the low efficiency of our institutes.

The book reveals Peter Kapitza's qualities that all his friends know well — his enormous courage, irrepressible vitality and humour. On humour, writing about theory and experiment, he quotes from the novel, *Gentlemen Prefer Blondes*, "that classical American work. . . 'Love is a good thing but a golden bracelet is forever'." His memory plays him wrong (or does he, as seems hardly credible, quote from a Russian translation?). What Anita Loos wrote in 1925 was "kissing your hand may make you feel very, very good but . . .". However, the point that Kapitza makes is that "theory is a good thing but a good experiment lasts for ever". Rutherford would have agreed, with the last part at any rate.

# Models and mergers in mathematical ecology

Oscar Kempthorne

*Theory of Population Genetics and Evolutionary Ecology: An Introduction.* By J. Roughgarden. Pp.576. (Collier-Macmillan: 1980.) \$24.95, £15.95.

THIS large book is an attempt to present the basic ideation behind two fields of biology — population genetics and ecology — and to initiate the merger between the two which has long been overdue. Population genetics had a pre-Mendelian start with Galton, but, of course, it was the discovery of the Mendelian processes that led to the useful application of concepts of mathematical probability to the subject. Over the same period that Fisher, Wright and Haldane were formulating mathematical theories of the genetics of populations, workers such as Kostitzin, Lotka, Volterra and Gause were developing ideas about the dynamics of populations. In writing this book, Roughgarden is following the tradition of Haldane, Fisher and Norton who took the initial steps in combining the two streams of thought.

Roughgarden's purpose is to formulate mathematical models that incorporate aspects of birth, ageing and death, and to establish the consequences of such models. The mathematics involved in doing this become rather complex, but there is no doubt that this is one of the necessary approaches to a greater understanding of many biological processes. The result of this is that it is now common — indeed necessary — for departments of biology to include members of staff who have had a rigorous training in both biology and mathematics. Roughgarden is obviously an exemplar; he has made a fine effort to give an overall picture of a complicated field.

His book consists of five parts. The first is concerned with the basis of the subject, and in it he develops the elementary theory of a simple infinite Mendelian population with a two-stage life. Individuals contribute according to genotype (but not sex) to male and female genetic pools, newborns arising by the random union of gametes. This leads into what Roughgarden calls "Wright's adaptive topography" (an unfortunate term), with the correct (but misleading) result that such a population will move towards maximum mean fitness. The rest of the opening part of the book is taken up with considerations of the fundamental theorem of natural selection for asexual populations — which has no genetic content at all — genetic drift (for a diallelic locus) and the neutrality controversy. This last chapter provides a good introduction to a somewhat obscure area.

I had anticipated that Part 2 would include detailed discussion of complex genetic systems. In fact, Roughgarden considers only models based on variation at

a multi-allelic single locus and two biallelic loci. Yet, even in this relatively simple case, what is really going on is far from clear (see Fig. 8.8, for example). This is followed by a rather curious chapter on natural selection and quantitative inheritance; the first half is purely biometrical and not Mendelian, the second does incorporate elements of simple Mendelism. Part 2 concludes with a consideration of Fisher's fundamental theorem — which is not at all as fundamental as Fisher thought — and a chapter on non-random mating, a reasonable introduction to inbreeding and assortative mating.

The next section of the book was, to me at least, the most disappointing. It deals with evolution in general, and in spatially varying and temporally varying environments, and with the development of altruism; few results having general implications have come from recent work in these areas.

Once again, in the first five chapters of Part 4, one soon gets involved in difficult integral equations. Here, Roughgarden considers the dynamics of an asexual population in what is a neat, but perhaps oversimplified, presentation. Finally, in this part of the book, stochastic environments are treated; here, it is a great surprise to find the use of Ito and Stratonovich stochastic calculus.

The final section of the book deals with

interacting populations. It starts with a consideration of competition between asexually reproducing populations and leads on to predator-prey models — a useful exposition. Then we are given chapters on coevolution (incorporating a single Mendelian locus and based mostly on Roughgarden's own recent work) and on niche theory and island biogeography.

My overall impression of the book is that it provides a useful but on occasions oversimplified picture of research in the field between 1910 and 1950. Its real value lies in that large portion which deals with more recent work, that undertaken over the past decade, and in this it will undoubtedly be of great value to specialists in mathematical ecology. A deep lacuna in the whole effort is the absence of real quantitative data and then the testing of models by reference to such data. Part of this is due to the immense difficulty of obtaining "hard" data on the dynamics of real ecological systems.

Theoretical ecology incorporating genetics is a young yet complicated area of biological enquiry. We must be grateful to Roughgarden for giving us a base from which to proceed. □

## Thermodynamics and macromolecules

S. P. Spragg

*An Introduction to Physical Properties of Large Molecules in Solution.* By E. G. Richards. Pp.298. (Cambridge University Press: 1980.) Hardback £18, \$29.50; paperback £5.95, \$9.95.

TO MANY teachers of biophysical chemistry it seems strange to note that over the past two decades instruction on the subject of macromolecules has progressed to a position of marked contrasts. On the one hand, structural descriptions of macromolecules are based on accurate methods of X-ray crystallography, so students persevere in understanding details of this technique. On the other, emphasis in the teaching of the properties of macromolecular solutions has moved slowly away from exact thermodynamic interpretations and so student interest in the fundamental understanding of thermodynamics has waned. It is a pity that some recipe cannot be found which convinces students that the three laws of thermodynamics provide a thread for connecting

many phenomena associated with macromolecular solutions.

The present book contains little philosophical discussion along these lines but it is particularly good at referring proofs back to the fundamental laws of thermodynamics without stating the laws as a starting point. The contents range over configurational statistics of polymers, helix-coil transitions and hydrodynamic properties of macromolecules, as well as providing sound introductions to molecular interactions of neutral molecules and polyampholytes. The lack of experimental results which direct the students' attention to the phenomena under discussion means that the book must be supplemented through lectures; for example, experimental results from the melting curves of nucleic acids would have formed a useful start to the discussion on helix-coil transitions. Further examples will come to the mind of other readers, but this criticism is minor and only serves to show that this book is mainly concerned

with theoretical treatments of problems.

It was particularly pleasing to find a chapter devoted to scattering of electromagnetic radiation (written by S. D. Dover), since some understanding of this phenomenon at a fundamental level is becoming more important as laser technology expands the possibilities of measuring molecular properties on very short time scales.

The book will provide a useful reference text for undergraduates requiring guidance in the application of chemical thermo-

dynamics to describing macromolecular properties. Further, like Professor C. Tanford's well known text on a similar topic (*The Physical Chemistry of Macromolecules*; Wiley, 1961), the content is such that it will also be of value to postgraduates with an interest in the subject.

*S. P. Spragg is Senior Lecturer in Physical Chemistry at the University of Birmingham, UK, with research interests in the solution properties of biological macromolecules.*

## New membranes for old

Harvey Lodish

*Cell Membranes and Viral Envelopes.* Edited by H. A. Blough and J. Tiffany. 2 volumes, pp.848. (Academic: 1980.) Both volumes £40, \$92.

MOST lipid-containing animal viruses bud from either the plasma membrane or internal membranes of infected cells. Much of our knowledge of the structure and assembly of membrane components has come from the use of defined virus model systems. These two volumes represent a noble and needed attempt to bring together reviews on the structure and function of both viral and cellular membranes and their constituents. There are chapters, written by recognized experts, on the basic physical and microscopic techniques used in membrane research, and on the biochemistry of viral and cellular membrane lipids, proteins and carbohydrates. In addition there are contributions on the structure and assembly of particular groups of viruses — influenza virus, retroviruses, Herpes virus and rhabdoviruses — though, oddly, none on the paramyxoviruses or arboviruses.

Most of the contributions to these volumes were written in 1974 and 1975. The end result is that the coverage of publications during the past five years is very erratic. Incredibly, the two chapters written by the editors contain references to very few articles published after 1976. What is worse, the editors apparently exercised little direction over the content of individual chapters, nor did they attempt to rewrite, up-date, or interrelate them. The predictable result is extensive redundancy of data and confusion between chapters.

As one example, the partial sequence of glycophorin used in the chapter on the structure and function of membrane proteins is taken from the 1971 preliminary report; there is no reference to the complete sequence published in 1975 or to the 1978 revised sequence. Oddly, the complete sequence is contained in the following chapter, "Carbohydrates in the Cell

Membrane". Further, in no contribution is there mention of the techniques of fluorescence photobleach recovery, now probably the most widely used method for the determination of the extent and rate of lateral diffusion of cell surface components.

The chapter on carbohydrates of viral envelopes was written in 1974, and is very dated, but some of the more recent structural work is contained in the following chapter, "Glycosylation of Viral Envelope Components". None of the contributions discusses recent work on the importance of proteolytic cleavages in the maturation of viral glycoproteins, such as the influenza haemagglutinin HA or the paramyxovirus fusion protein F. The contribution "Synthesis of Viral Proteins" was also written in 1974-1975, before the site of synthesis of viral glycoproteins in the rough endoplasmic reticulum was known; this chapter, unfortunately, is now largely of historical interest only. Like several others, it contains a one-page addendum which mentions some published work up to the beginning of 1977, but there still remains an inexcusable three-year delay before even this was published.

Some of the individual reviews dealing with more recent developments are of high quality. Many others would have been quite useful had they been published within a year or so of writing, surely a more reasonable lag time. These include those on virus receptors; on influenza virus; on structure and on synthesis of membrane and viral lipids; and on membrane changes in virally transformed cells. The fields covered by this book are expanding very rapidly; as a consequence, these reviews will not be of much value to the contemporary student or researcher. It is indeed unfortunate that the considerable effort expended in writing this book has been largely wasted, as current reviews of these topics would be valuable.

*Harvey Lodish is Professor of Biology at the Massachusetts Institute of Technology, Cambridge, Massachusetts.*

## Geothermal maps

Philip England

*Atlas of Subsurface Temperatures in the European Community.* Compiled by R. Haenel with co-authors. Large format, pp.36+43 maps. Commission of the European Communities/Th. Schäfer: Hannover, 1980.) DM 120.

THE production of subsurface temperature maps for an area the size of the European Economic Community is an undertaking that requires a degree of faith. If it can be assumed that the available, sparsely distributed, temperature and thermal conductivity data adequately characterize the near-surface heat flow of the region (and that this is not perturbed by fluid motion), then it requires only a knowledge of the subsurface geology, and of the thermal conductivity and heat generation of the major lithologies, to extrapolate measured temperatures outward and downwards to make the kind of map this book contains.

These maps are each about 40 cm × 50 cm in size. Seven are 1:5,000,000 maps of subsurface temperature distributions beneath Europe at depths between 500 m and 5 km; six show subsurface temperatures at 1 km for the countries of the EEC; and some 20, with scales of between

Leo Szilard: *His Version of the Facts*, edited by Spencer R. Weart and Gertrud Weiss Szilard (for review see *Nature* 278, 285; 1979) has been re-issued in paperback by the MIT Press, price \$7.50, £4.95.

1:500,000 and 1:75,000, indicate subsurface temperatures in areas of geothermal interest where the density of subsurface temperature measurements is highest.

Compiling these maps has clearly involved assembling vast amounts of subsurface temperature data (otherwise not readily accessible), and where the density of these observations is high — in the upper kilometre or so of regions of known geothermal potential — the maps may be regarded as reasonably accurate summaries of the available information. Their use is limited, though, when the density of observation is low and when extrapolation over depths of several kilometres is required.

Anyone contemplating buying this book should look first at Plate 2, which shows the density of the available heat flow information in the EEC, and at Plate 39 which indicates the amount of information provided by boreholes. Next they should read, in any one of six languages, the four-page introductory text which gives a brief exposition of how the maps were compiled and of the pitfalls involved in making the kind of extrapolation outlined above. (One point not dealt with adequately is the error involved in assigning values of conductivity and heat production when extrapolating temperatures downwards; the compiler's assumption that the likely uncertainty in these parameters is 10–15% is a wildly optimistic one, and leads him to place misleadingly small error bars on the temperature estimates that he makes.)

Having taken these steps one should be convinced of the difficulties involved in predicting subsurface temperatures from the information available at present, and hence that this book is of little use as a predictor of geothermal resources. The book's remaining attribute, on which it should be judged, lies in the compilation of information that it represents. It is a shame, therefore, that the introduction is so cursory, that so little indication is given of the reliability of the data, and that it was thought necessary to present the information in this elaborate guise.

Philip England is a Research Fellow in the Department of Earth Sciences, Bullard Laboratories, University of Cambridge.

## Herbal facsimiles

Sandra Raphael

*Herbarium Apulei Platonici* (Vol.I) and *Herbolario Volgare* (Vol.II). Facsimile reprints. Introductions by Erminio Caprotti and William T. Stearn. Pp.CXXII + 566. (Edizioni Polifilo: Milan, 1979.) Both volumes L.85,000.

A NEW pair of facsimiles reprints the first Latin and the first vernacular herbals published in Italy, the former in 1481, the latter in 1522. The 1481 book, probably the earliest illustrated herbal printed, is the *Herbarium* of Pseudo-Apuleius, a Graeco-Roman compilation with mediaeval trimmings, surviving in a multitude of manuscripts that indicate its status as a standard source of information on medicinal plants. The crude, diagrammatic woodcuts can have given little help in the identification of the plants described.

The 1522 *Herbolario Volgare* took both

its text and its illustrations from the *Latin Herbarius* printed by Peter Schöffer, Gutenberg's successor, in 1484. The text is another miscellany from an unknown hand, but its pictures are a decorative improvement on those of the Apuleius. The Iringo (sea-holly) is shown here, a plant whose candied roots were regarded as an aphrodisiac as late as the seventeenth century.

Professor Stearn's introductory essay appears in both Italian and English, and the books are fine examples of the exquisite printing of Mardersteig's Stamperia Valdona.

Sandra Raphael is a Senior Editor in the Dictionary Department of Oxford University Press. Her book on illustrated herbals, title?, written in collaboration with Wilfrid Blunt, was published late in 1979.

**CDello Iringo.**

**Cap.LXXVI.**

**L**O iringo sic caldo & humido nel primo grado: Et la sua humidita e maggiore della sua calidita: & quelli che usano la radice condita cō melle moltiplica il sperma: & fa al coito: & allo drizare della uerga: & fa bon nutrimento: Dice serapione & Auicena: Et le radice de iringo cō uno pocho de specie aromatiche si māgiano: ouero con melle o zucararo & cinamomo si acōciano: Lo iringo sic una sorte de spina le foglie delloquale si agionge

18/25 December 1980

# Britain, France and nuclear weapons

Between now and 20 January, when Mr Ronald Reagan will be inaugurated as president of the United States, much important business elsewhere will be conducted in a vacuum. So much is clear from last week's meeting of the NATO Council in Brussels. Many of those present seem to have been as interested to know whether their old colleague, General Douglas Haig, will finish up as United States Secretary of State as in the prospect that threats of economic sanctions against the Soviet Union would deter an invasion of Poland. Yet vacua have their benefits. As boxers tend to free-associate in the nervous minutes before the beginning of a fight, so politicians and others in the West have been talking openly about some of the issues on which American influence will again be dominant in January — defence, arms control and the like. In Britain, this unaccustomed free speech has been mixed with the wild talk inseparable from the accession of Mr Michael Foot as leader of the British Labour Party, for Mr Foot used to be a staunch supporter of unilateral nuclear disarmament for Britain, and has not yet renounced his former views. The Campaign for Nuclear Disarmament can boast of more recruits in the past few months than in the past several years.

Economic issues apart, the most obvious uncertainty is Mr Reagan's position on arms control, and on his plan to renegotiate the Salt II agreement. During the election campaign, his position shifted steadily, from outright repudiation to renegotiation. Soon after 20 January, it should be possible to tell where he now stands, but the signs are encouraging. The Soviet Union has not slammed the door on further talks about the agreement that President Carter shrank from fighting through the US Senate. His successor must by now know the strength of opinion in Europe, especially in Germany, about the need for agreement on short-range as well as strategic nuclear weapons. Anxiety about Poland has only sharpened suspicions that the stability engendered by mutual nuclear deterrence has its drawbacks. With nothing worth mentioning happening at the Madrid conference on the Helsinki accords, Mr Reagan is likely to have calculated that arms control is not, as he once supposed, the wishy-washy plaything of liberals but a considerable political opportunity. That, at least, must be the hope.

Will governments elsewhere be capable of similar (and still unproven) flexibility? The need is most urgent in Britain, as the defence debate in the House of Lords on 3 December showed. Since the invention of nuclear weapons, there have been two British positions on nuclear defence — the belief (shared by all governments in office) that an independent nuclear deterrent is a necessary part of British policy. This is the belief which led the Callaghan government to fit the Polaris submarine missiles with new warheads (at a cost estimated at £1,000 million) and the present government to order a fleet of six Trident nuclear submarines (at a cost of £5,000 million spread over the next ten years). At the other extreme is the view that British bombs are not a strength but a weakness, and should be dismantled. The unilateral position is not homogenous — some ask merely for the abandonment of British nuclear weapons, others would refuse to provide bases for US nuclear weapons or even withdraw from NATO. Nor are the unilateralists entirely wrong-headed in their views. Unilateral nuclear disarmament would bring certain benefits. The snag, which hitherto has far outweighed the advantages, is that there would be a profound change in the character of British political relationships across the Atlantic and across the Channel — and no assurance of British immunity from the consequences of foreign wars.

The novel development is that, in Britain, there is a growing body of opinion sandwiched between the two conventional extremes. In the House of Lords debate, people such as Lord Zuckerman (once Chief Scientist at the Ministry of Defence) and Lord Chalfont (Mr Harold Wilson's Minister for Disarmament) poured cold water on the decision to replace the Polaris submarines with Trident. "If we can afford it, so be it", said Lord Zuckerman, who knows as well as the next British taxpayer that the government's survival will soon depend on its success in cutting public expenditure. The case against the Trident replacement unites an impressive range of interests. The military (represented, for example, by Lord Carver, a distinguished field marshal) would prefer to see the Trident money spent on conventional forces. Strategists (like Chalfont) argue that weapons other than Trident missile submarines would be cheaper and no less effective. None of this implies support for unilateral disarmament — the denial of British bases to US nuclear warheads (in aircraft now, in cruise missiles sometime after 1983), for example. What has happened is merely that entirely sensible opinion has begun to question the most conspicuous cornerstone of British defence policy in the period since 1945.

The British government has been slow to see the way the wind is blowing, or to recognize the advantages of following Mr Reagan's apparent willingness to make the best out of accommodations with his critics. The most immediate embarrassment of the Trident programme is its cost, probably grossly underestimated at £5,000 million. Can it make sense that a government whose chief failure since its election eighteen months ago has been its failure to cut public expenditure should now take on a capital commitment on such a scale, more than half the cost of the US Apollo programme? The decision might be more easily justified if (as some Apollo-builders held in the 1960s) building the Trident submarines would bring uncovenanted technical innovations, but the objective is largely to replicate the nuclear submarines already being built in the United States. It is no wonder that there has been a revival, in the past few weeks, of the old dream of an Anglo-French cruise missile system. That would be cheaper and politically powerful.

These are narrow arguments. The broader question of whether countries such as Britain — France is the only other example — should hang on to independent nuclear forces is more divisive. The conventional British statement of the case is that nuclear weapons are a contribution to collective defence and an assurance of influence in international negotiations, about disarmament as well as making war. The French view, more iconoclastic, is that French security depends in the last resort on French arms. Both arguments are stiffened by chauvinism. With time, each is weakened. Each of them is less convincing as strategic technology becomes more sophisticated. Yet in Western Europe there is a crying need that the European Community should soon acquire what it should always have had — a foreign policy and a defence policy to go with it. Is that where Britain and France may pool their nuclear ambitions after 20 January?

## Nature publication date

As in previous years, this issue of *Nature* (dated 18/25 December) is the last to be published in 1980. Because there are 53 Thursdays in 1981, the next issue, published on 8 January, will be dated 1/8 January 1981.

# US research budget now in better shape

## Dying Congress restores earlier cut-backs

*Washington*

It may not last, but in contrast with previous years, when President Carter's requests for additional funding for science were trimmed back by Congress, the final 1981 research budget looks in even better shape than when it was presented in January 1980.

The Administration revised its initial request in March, reducing a proposed growth in spending on research and development from 11 to 8 per cent. But while Congress has agreed to cuts in other areas of social spending, research and development has been relatively protected.

Last week, for example, when Congress finally agreed to an appropriations bill covering the budgets for 23 assorted federal agencies, only three — the National Aeronautics and Space Administration (NASA), the National Science Foundation (NSF), and the American Battle Monuments Division — received more money than they had asked for.

As in previous years, legislators have been kind to the budget of the National Institutes of Health (NIH). Although the final figure is yet to be agreed, the House has approved an NIH budget of \$3,616 million, and last week the Senate gave its approval to a \$3,686 million budget. Whichever figure is finally decided upon, it will be higher than the \$3,581 million initially requested, and will result in a 5.5 to 7.5 per cent increase in NIH's budget over last year.

In the Department of Energy, threats to the basic research budget — which includes funding for high-energy physics and nuclear physics — were successfully fought off during the summer. The final sum for items under the responsibility of the department's Office of Energy Research will be \$1,145 million, only slightly less than the \$1,203 million requested, with the major reduction being the postponement of improvements to facilities at the national research laboratories.

Only in the case of the Department of Defense, for which the Administration had originally requested a hefty 17 per cent increase in spending on basic research, is the final figure likely to be substantially lower. Congress has approved an appropriations bill which will cut this increase to 12.5 per cent, reducing the planned real increase from 8 to 3.5 per cent. The final figure may be even less, since Congress has also asked the Pentagon to impose further unspecified cuts totalling 4

per cent across the whole of its research and development budget. In the case of NASA and NSF as well, the final figures may be reduced by a requirement that the Office of Management and Budget distributes a further 2 per cent cut across all the agencies covered in the appropriations bill.

Congress has also forced several significant changes in the content of the Administrations proposals for federally-sponsored research programmes.

At NSF, for example, sustained pressure from Senator Edward Kennedy has led to the agreement to introduce a new programme to boost women and minority scientists. Mr Kennedy had added his own "Women in Science" bill to the Senate version of the NSF appropriations bill; and the House finally agreed to a \$30 million programme which will include more than 100 grants for women scientists extra to those which would be otherwise awarded. The NIH budget, on which a final total has yet to be settled, includes an extra \$35 million for training grants which the Administration had suggested be cut back to enable the number of new and

competing research grant awards to be kept constant.

A large part of the increase in NASA's budget will go to cover the additional costs of the much-delayed space shuttle. However, Congress is also becoming increasingly concerned about cost and schedule over-runs in virtually all of the space science programmes.

As a result, Congress has directed NASA to ensure that it receives approval from the National Academy of Sciences before making any substantial programme changes. This move, opposed by several NASA administrators, is supported by Congress as a way of ensuring an adequate response to any future technical difficulties.

Despite the set-backs being experienced by the various space science programmes, almost all have escaped the congressional budget process relatively unscathed, including the proposed new gamma-ray observatory. However, there were warnings that some projects could still be halted through budget rescissions early next year when the new administration takes over.

## Oil, shale or mirage in West Siberia?

The strange story of the supposed Bazhenov oil field in western Siberia, with its reserves of over 600,000 million tonnes of oil, reached the world's newspapers two weeks ago at a particularly sensitive moment. The threat to world oil supplies posed by the Gulf War, and Western contingency plans for a further technological embargo on the Soviet Union should Soviet troops be ordered into Poland, and the impending OPEC meeting in Bali made the announcement of the new field, with reserves surpassing world proved oil reserves, a major consideration for politicians and oil magnates alike.

The report on the Bazhenov field came from Petrostudies, a two-man Swedish team which monitors all open Soviet publications on the oil industry. The consensus of expert opinion, ranging from the CIA to the Soviet oil industry, is that its report is an exaggeration. One French expert went as far as saying that it would amount to a "geological miracle". Petrostudies, however, remains adamant about the size of the find, but is now prepared to concede that a considerable proportion of the oil may not be recoverable.

Challenged with a Soviet statement that the deposit was not oil but shale, Petrostudies director Manlyo Jermol replied that the Bazhenov shale was scientifically important because it contained liquid crude. Until now, he said, it had been believed that such oil was to be found only in porous rocks. He cited the Soviet

geologist, Ivan Nesterov, director of the West Siberian Research Centre for Oil Prospecting who, in 1978, had announced that Soviet research had refuted the old text-book assertion that shales cannot accumulate free oil.

A few days before the Petrostudies announcement, Nesterov was interviewed on Moscow radio in connection with the publication of the guidelines for the new Five Year Plan. On this occasion he was vague about the West Siberian potential. The fields now in production yield more than 300 million tonnes of oil and gas condensate per year, he said — amounting to about half the total Soviet output. But since two thirds of all the fields discovered in the area have not yet been touched, and only one fifth of the oil-bearing region of West Siberia has been explored it is difficult to make reliable estimates of the reserves. Extraction costs, he pointed out, are soaring, the costs of erecting a rig have risen 30 per cent in the last five years, and it has proved impossible to sustain the original growth rate. While maintaining that Western talk about Soviet oil running out in the near future is "highly premature", Nesterov's talk was couched in cautious terms. During the next five years, he said, the Soviet Union will be able to meet its own requirements and its commitments to its trading partners. For the longer term, he gave no hint of any bonanza — shale or otherwise, of the type suggested by Petrostudies.

**Vera Rich**

The one potential casualty, the National Oceanic Satellite System (NOSS) — the proposed successor to the SEASAT satellite — will receive an extra \$6.4 million through the research budget of the Department of Commerce's National Oceanic and Atmospheric Administration (NOAA). NOAA has also received an additional \$1 million for manned undersea facilities, but had \$2 million for acid rain research cut from its budget.

In biomedical research, Congress has rejected proposals from both the House and the Senate for greater supervision of NIH. A bill continuing authorization for the National Cancer Institute and the National Heart, Lung and Blood Institute was passed on 5 December without either the provision for a Presidential Commission on biomedical research priorities, proposed by Senator Edward Kennedy, or controversial new authorizing legislation for the remaining nine research institutes which had been proposed by Representative Henry Waxman.

Cuts in the Defense Department's proposed research programme could set back the growth of ties between the military and universities that have been developing over the past four years, according to Pentagon officials, who warned that in particular proposed new programmes for the Department of the Army may have to be cut back.

Nor will the Defense Department be receiving the hoped-for funds to construct a new production facility for binary chemical weapons. This was deleted by members of the Senate from next year's appropriations bill, on the grounds that if the United States is to resume chemical weapons production, this should be a presidential not a congressional decision.

David Dickson

## Nuclear safety

### European hazards

Brussels

European nuclear power stations are not as vulnerable to operational errors as the one involved in the accident at Three Mile Island, but there is plenty of room for improvement in safety measures in nuclear power stations in the European Economic Community. This conclusion comes from a report submitted to the European Commission's Interdepartmental Coordinating Committee on Nuclear Safety (CCNS). Many of the report's proposals are disputed by the committee in an accompanying reply.

The report comes from a four-man group set up by the European Commission after the Three Mile Island incident. The members of the group were H. Dunster, Deputy Director General of the UK Health and Safety Executive, Professor Latzko of the Technische Hogeschool Delft, Professor Smidt of the Institut für Reaktor Technik der Universität Karlsruhe, and Mr

S. Villani, Director General of the community's Joint Research Centre.

Conditions similar to those which led to the Three Mile Island accident have occurred on several occasions in Europe — the report criticizes the fact that these went almost unnoticed, and calls for a data bank recording all abnormal events in European nuclear power stations.

The siting of nuclear power stations is becoming increasingly politically sensitive in Europe. The report stresses that siting has only a limited part to play in protecting the population, but that there should be a consistent approach among member states to siting nuclear plants, especially in areas close to national borders.

The group also considers that more should be done to minimize the effects of any accidents that may occur: the Commission should study the emergency procedures operating in the various member states, there should be a review of the emergency plans made by the power station operating organizations before they are licenced to operate, and more attention should be given to ways of keeping the public informed in the event of an accident.

The European Commission is criticized for not responding rapidly enough to changing nuclear research needs, for setting up cumbersome committees, and for providing those committees with inadequate technical and administrative services.

According to the Interdepartmental Coordinating Committee, many of the recommendations in the report actually tie in with actions already taken by the Commission, or actions already under consideration. But the rather half-hearted attitude towards nuclear power expressed in the report is not welcomed by the committee. The report says: "no amount of care will totally eliminate the risks of this (nuclear), or any other sort of energy . . . (but) . . . we are finally led to the belief that nuclear sources should continue to play a significant part in the supply of Europe's energy."

Jasper Becker

## Fast reactors

### Low morale

Staff morale may be as much a threat to the British fast reactor programme as the prospect of a public inquiry on the project. The latest sign of this is the resignation of Mr Jack Moore, coordinator of the fast reactor programme at the UK Atomic Energy Authority (UKAEA), at the end of the year. Mr Moore, who is 57, is leaving to take up a post with Motor Columbus engineering consultants in Switzerland. He said earlier this week that at UKAEA he was unlikely to see his work of the past seven years come to fruition before his retirement.

Mr Moore's resignation highlights two potential problems for the staffing policy of the fast reactor team. Although no other

senior staff are reported to be leaving, further delay in a commitment to build a fast reactor may prompt others to go. The second problem is that of the age structure of the design team. Although the UKAEA has been expanding the team by bringing in young people, previous recruitment policies have left a noticeable dearth of people in their forties. When the senior staff retire or leave, their posts will have to be filled by much younger people.

A government statement on the commercial demonstration fast reactor has been expected since the summer. Sir John Hill, chairman of the authority until the end of the year, submitted a proposal to the government a year ago. Mr Moore expects that the government will respond shortly but that it will not make a final decision at this stage. One complication is that the government has not yet responded to the French proposal that Britain should by into commercial exploitation of Super-Phénix.

Meanwhile, the Nuclear Power Company is nearing the completion of a detailed design study, which Mr Moore claims will be superior to current French and Russian designs. The UKAEA would like to submit it to the Central Electricity Generating Board and potential reactor manufacturers so that a site could be chosen and a total project proposal put to the government.

Judy Redfearn

## Satellite communications

### Free for all ahead?

Washington

While the future of US remote-sensing satellites remains entangled in controversy (see *Nature* 14 August), the use of telecommunications satellites is poised for a dramatic expansion.

The Federal Communications Commission (FCC) in Washington has given permission for the launching of 20 new domestic communications satellites, which are likely to increase the capacity of the present system by a factor of four by the mid-1980s.

At least one newspaper company is discussing plans for a nationwide system of locally-produced newspapers linked by satellite, while the Communications Satellite Corporation (Comsat), which owns three of the nine communications satellites at present in orbit, has proposed starting a four-satellite system beaming television programmes directly to private homes within the next few years.

FCC approval for the authorization of the new satellite launches was given unanimously, part of what commission chairman Charles Ferris described as an "open-entry policy" to provide satellite capacity to all who want it.

A separate report prepared by commission staff, for example, has recommended that direct-broadcast satellite television services should be subject to the minimum of regulation, in

the light of competitive pressures from conventional television stations and cable television networks.

The commission is also expected to publish for comment a proposal for squeezing more domestic satellites into geosynchronous orbits, perhaps by reducing the separation of higher-frequency satellites from four to three degrees of longitude.

Such a change, says FCC, would allow the launch of an additional six satellites which had been promised to the commission, but which could not be authorized because of the shortage of available slots.

The launch of the 20 new satellites is likely to result in an increase from 160 to 612 in the number of satellite communications channels available by 1985. Each channel can transmit 1,000 telephone channels or a single television channel.

The new satellites will also create the first major challenge to the giant American Telephone and Telegraph Company (AT&T) in the field of long-distance communication. Two competing companies — General Telephone and Electronics Corporation and the Continental Telephone Corporation — are building their own satellites. AT&T, General Telephone, Southern Pacific Communications Corporation and Hughes Communications will each be constructing their systems for the first time, each having been given permission to build three satellites and launch two.

Local newspaper production could be revolutionized by plans that the Gannett Company is said to be developing for a national newspaper produced in Washington, but beamed to the presses of some of Gannett's 82 local newspapers.

Satellite transmission is already used by the *Wall Street Journal* to print seven editions simultaneously throughout the country. Although no official confirmation has been given of Gannett's plans, it is reported that the initial investment would be about \$100 million; some commentators have pointed out that setting up a single newspaper distributed throughout the country would provide Gannett with the opportunity to become a major voice in national affairs.

Comsat's plans for a satellite-based television network are included in a set of comments which the company has submitted to FCC as part of its preparations for the Region 2 Administrative Radio Conference of the International Telecommunications Union, due to be held in the summer of 1983.

Four satellites would be used to cover the United States, each covering a different time zone, with the most westerly satellite also broadcasting to Hawaii and Alaska. The service would be operated by Satellite Television Corporation, a newly-created subsidiary of Comsat. The market for direct-broadcast satellites is expected to be tested with the modification of two existing spacecraft designs.

David Dickson

## Ariane development

### More trouble

Ground tests of the principal rocket motors of Ariane, putative launch vehicle of the European Space Agency (ESA), have shown brand-new oscillations in the burn — and set the test programme back by a second three months.

Ariane's first test launch in late 1979 reached the planned trajectory, but the second — in May 1980 — ended moments after lift-off with a high frequency oscillation and loss of pressure in one of the first stage engines. A look back at the data for the first launch showed the same oscillation, but at low amplitude; and a re-run of the data accumulated during ground tests showed the same fault.

In October this year, ESA announced that the oscillations (at 2,300 Hz) could be cured by improving tolerances in the manufacture of the injectors, devices like a watering-can rose that mix the fuel and oxidant. This hypothesis will be tested at the end of this month, when new high precision injectors are tried for the first time. Meanwhile a new oscillation has appeared — at 2,700 Hz — and this sets in even with injectors that previously showed no sign of the vibration. While the 2,300 Hz problem "can be regarded as rectified" says ESA hopefully, the 2,700 Hz oscillation "is the subject of thorough investigation and action which still needs some time to complete".

Burn oscillations (called "buzz" or "screaming") are the *bête noire* of liquid fuel engine design and can destroy the engine if they reach high amplitude. One solution is completely to redesign the injector; another is to set Helmholtz resonators, tuned to the critical frequency, into the side of the combustion chamber in such a way as to absorb the oscillation energy.

Solutions such as this, however, verge on complete redesign of the engine — but this may be necessary in the end. The engines were originally designed for the French sounding rocket Diamant (in which similar instabilities were met and solved), but they

were stretched to the limit to meet Ariane's specification of 61 tonnes-weight thrust. The next series of engines, for a bigger Ariane, is based on a different design.

So it is seriously being questioned whether Ariane can meet its first commercial commitments: to launch the French MARECS B and SERIO 2 marine communications and meteorological satellites (which would go up together) and Intelsat V F6. These satellites, and the ESA X-ray astronomy satellite EXOSAT, were originally due for launch in 1981.

For the moment, ESA hopes to have the third test launch in June 1981, and the fourth in the autumn, beginning the commercial series later in the year. If, however, as some fear, the Ariane engines are inherently "marginal", redesign and retesting could take at least a year, and lucrative launch contracts might be lost to American competition. The lead that Ariane appeared to be establishing over the space shuttle — beset by its own problems but now believed to be running smoothly — is narrowing fast.

## Halley missions

### NASA to go?

#### Washington

Can the new US Administration be embarrassed into mounting a mission to Halley's comet when it passes through the Solar System in 1986? The proposal has already been passed to president-elect Ronald Reagan from scientists in his home state of California. They point out that the European Space Agency, the Soviet Union and Japan all have plans for separate Halley missions — and that for the United States not also to go would be a major blow to national prestige.

Revised plans for a Halley fly-by were developed earlier this year at the Jet Propulsion Laboratory (JPL) in Pasadena, run for the National Aeronautics and Space Administration (NASA) by the California Institute of Technology (Caltech). Following last year's rejection by the White House of a request for funds to develop an ion-drive — for which money

## Beyond Saturn

Saturn, as seen by Voyager 1 on 16 November, four days after the encounter. Some of the dark spoke-like ring features (*Nature* 4 December) are seen as bright patches due to scattering of sunlight from particles within them. Voyager 1 will be monitored to as great a distance as possible in an attempt to detect the boundary between interplanetary and interstellar space, where the "solar wind" becomes undetectable. Voyager 2 will reach Saturn on 25 August 1981, Uranus in 1986 and Neptune in 1989.

has since been allocated by Congress, but too little and too late — the revised mission would rely on a ballistic launch, limiting its ability to manoeuvre near the comet.

Many JPL scientists still think the mission would be worthwhile, a conclusion backed up by the mission's science committee, headed by Professor John Ververka of Cornell University. And the proposal has already been put to Mr Reagan by Caltech trustee Earle M. Jorgensen, a Los Angeles businessman and close friend of the president-elect.

Scientists at JPL are stressing the question of national pride, one aspect of the space programme that they feel has received relatively little support from the Carter White House. But other members of the space science community are worried that political support for a fly-by mission could prejudice funding for NASA's own favourite scientific project, the Venus Orbiting Imaging Radar (VOIR).

In an unusual move (considered by many a pre-election gambit to win Californian votes), the White House announced in October that it was planned to request funds from Congress for VOIR when the 1982 budget proposals are submitted in January — implying a rejection of the revised Halley plans.

From the scientific point of view, VOIR is reckoned to be more fruitful than the Halley intercept. Members of NASA's space science advisory committee have already stated that they find the possibility of losing VOIR and getting the Halley mission instead to be "extremely distressing".

In addition, however, to the financial attraction — the present Halley plans would make substantial use of instruments developed for the Voyager missions, and its total cost of \$250 million would therefore be only about half that of the proposed VOIR — JPL scientists point out that the chance to observe the comet is a "once in a lifetime opportunity".

Officials from the European Space Agency (ESA) are watching the new developments with some concern, since they feel that a NASA project might well overshadow the more modest goals of ESA's own Halley mission, Giotto, particularly since the latter may not be able to produce photographs of the comet comparable to NASA's.

A substantial NASA involvement in the European effort is now unlikely. Two weeks ago, ESA's space science committee decided to keep the launch a European affair, using the French Ariane rocket, and were therefore not interested in the US offer of using a Delta launcher in exchange for payload space.

US scientists will not be entirely excluded from the European mission. A number are listed as co-investigators in experiments submitted for inclusion in the spacecraft. And ESA is still negotiating terms for Giotto to make use of NASA's deep space tracking network.

NASA, however, is uncomfortable about accepting the unusual role of second fiddle, and supporters of a US mission are emphasizing this possibility in efforts to generate support. Adding the Halley mission to the 1982 budget for NASA would affirm to the world in a "spectacular and dramatic way" that US leadership in high technology stands unsurpassed at the frontiers of knowledge, according to a statement published in the *Congressional Record* by conservative Republican Senator Strom Thurmond. Another supporter is ex-astronaut Senator John Glenn.

If the mission is given the go-ahead, its planners will have a delicate balance to weigh up. Scientifically, more data will be obtained from intercepting the comet after it passes through its perihelion, since solar heating will stimulate the discharge of gas and dust particles. But politically an earlier intercept might be more attractive, as this would pre-empt both the European and the Soviet post-perihelion encounters.

Top NASA administrators are also said to be concerned about the risks of the mission — if the spacecraft is hit by a dust particle there might be no scientific return at all. Scientific and political priorities are therefore likely to meet head-on; nobody is predicting the outcome.

## Polish universities

### Union snag

The drafting commission for the new Bill on Higher Education in Poland met for the first time two weeks ago, under the chairmanship of Professor Zbigniew Redich. The commission was set up by the Minister of Science, Higher Education and Technology, Dr Janusz Gorski. A few days previously, Warsaw University students had staged a sit-in in one of the main buildings of the university to express their lack of confidence in the minister.

The two events are not unconnected; the new bill will give Polish universities considerably more autonomy and a more democratic form of self-government which will include student participation. The two hundred students who occupied a hall in the university's Kazimierzowski Palace were protesting, first and foremost, against the difficulties they are encountering in registering the new Independent Students' Union (NZS). Since students are not "employees", they cannot register as an independent trade union under the Gdansk accords. The first draft of the ministry's "instruction" permitting registration of NZS proved unacceptable to the Warsaw students, although it had been worked out with the participation of NZS delegates. When the ministry negotiator suspended talks with NZS, on the grounds that he must first consult the (now greatly depleted) Socialist Students' Union, NZS considered that the ministry had broken

off negotiations unilaterally and began their sit-in.

After occupying the hall for two days, the students won what they described as a partial concession only — a new ministry instruction on registration to come into force on 20 December. This should allay at least one fear — that without legal status, NZS would be unable to participate in the new "self-government" system of the university. Demands for a national NZS delegate meeting on student problems and for the publication of their grievances in the press were not met.

Neither the concessions by the minister nor the conciliation efforts of the university rector, Dr Henryk Samsonowicz could persuade the students to end their sit-in. Ironically, in view of the fact that NZS cannot legally be a trade union, it ended its protest only in response to a call for restraint issued by the Independent Trade Union Confederation Solidarity.

Vera Rich

## Fissile material

### Counting wrong

Are eleven kilogrammes of highly enriched uranium missing from Dounreay, the UK Atomic Energy Authority's (UKAEA) fast reactor research establishment in North Scotland? The authority cannot say. The amount appears in this year's tally of "materials unaccounted for" (MUF), and is something of an embarrassment. According to the UKAEA, the quantity is within measurement errors on a large throughput, but the throughput cannot be revealed for security reasons and the errors have not been calculated. So it is difficult to give significance to the figure.

All MUF figures announced last week lack error estimates because, an official said on Monday, "errors would have to be combined from many completely different processes and sources".

Nevertheless the 11 kg "loss" at Dounreay was near enough to a critical mass to give the authority pause. In the first three years for which MUF figures were announced, the MUFs at Dounreay for highly enriched uranium were +2.8 kg, +3.7 kg, and +0.3 kg, all indicating paper gains of the material. However, Dounreay was not reprocessing fuel for much of that period, and the present figures relate to the first year (since MUF accounting began) when fuel from the now closed Dounreay fast reactor was being reprocessed.

The figure amounts to a difference between the quantity of  $^{235}\text{U}$  estimated to be on the site at the beginning of the year and the quantity estimated at the end, taking into account traffic on and off site. But much of the  $^{235}\text{U}$  at the beginning was in the form of irradiated fuel rods, and so inaccessible to measurement. The amount in the rods was estimated using knowledge of their position and operating time in the

Dounreay fast reactor, and of the original composition of the rods. At the end of the year, some of these rods had been through reprocessing: here  $^{235}\text{U}$  can be measured easily only at the end of the flow, and by neutron activation analysis in the cans (which are stripped off at the beginning of the process).

When the 11 kg accounting loss was discovered, great efforts were made to recalculate the quantity and check measurements. The new figure was different (the authority will not release it) but it was agreed to keep to the original accounting value. However, the difference was great enough to indicate that the uncertainties in the original estimate were of the same order as its value — about 10 kg. For example, the recalculated figure for  $^{235}\text{U}$  in the original rods was 2 kg different from the first estimate.

However, still no calculation was made of the uncertainty, or "error", on the quantity. And this despite a statement a year ago by Dr A. G. Hamlin, director of the UKAEA Nuclear Materials Accounting Control Team, that "in order to determine whether MUF is really indicative of diversion of material, the safeguards authorities need to know, among other things, the expected level of errors. . .".

Robert Walgate

## US research planning

### NIH reprieved

Washington

The National Institutes of Health (NIH) have avoided the threat of new legislation which would have placed much closer congressional surveillance and control on their research programmes, proposed earlier this year by the House of Representatives health and environment subcommittee (see *Nature*, 22 May).

After intense opposition from medical schools and research institutes — and despite the support of the Secretary of Health and Human Services, Mrs Patricia Harris — proposals put forward by Subcommittee chairman Henry Waxman were mostly dropped when the bill was agreed in final form by the House and the Senate.

Also dropped were equally controversial proposals put forward by Senator Edward Kennedy on the Senate side for a Presidential Commission on biomedical research priorities. Senator Kennedy had wanted to attach this to legislation which re-authorizes the operations of the National Cancer Institute and the National Institute for Heart, Lung and Blood, the only two of NIH's eleven institutes at present requiring such legislation.

NIH themselves opposed both innovations, but were told by Mrs Harris to sit on their hands. Opposition was subsequently led by groups such as the American Association of Medical Colleges, which argued that NIH should be given the greatest possible freedom to

decide on their research strategies.

NIH did not, however, escape completely unscathed. Included in the authorization bill are requirements for additional administrative arrangements covering diabetes research — a pet subject of retiring health subcommittee member Senator Richard Schweiker, expected to become Mr Reagan's Health Secretary — and for research on digestive diseases. NIH officials feel that one disadvantage of the changes proposed by Congressman Waxman is that regular re-authorization of NIH research funds makes it easier for such provisions to be attacked by individual congressmen.

David Dickson

## European environment

### Small gains

Brussels

Agreement has still not been reached by the Environmental Council of the EEC on two pieces of legislation: one concerning the prevention of industrial accidents and the other on the level of mercury discharge. However, new controls on whale imports, the recycling of waste paper, and wildlife habitation have been accepted.

At the meeting in Brussels on 12 December, the so-called "Séveso Directive" again foundered on the French intransigence over transfrontier notification procedures. It had been proposed that information on potentially hazardous plants near frontiers should be made available on a Community basis. The French would prefer notification of neighbouring states bilateral — an idea swiftly rejected by Belgium and Luxembourg. This disagreement is bound to step up the campaign against French nuclear reactors near the Belgium and Luxembourg borders.

The directive on mercury is also meeting resistance from France and Britain. The UK delegation insists that environmental quality objectives be used instead of standard emission limits to measure pollution. In the draft directive — the first to be based on the controversial directive on the control of discharges of dangerous substances into the aquatic environment — it was suggested that the United Kingdom stick to its use of quality controls while the other EEC states use the limit value approach. The French, however, object to this, feeling that pollution abatement costs should be the same throughout the Community. Both this and the industrial accident proposals will now go back to the Committee of Nine's Permanent Representatives for further discussion.

On the bonus side, from 1 January 1982 imports of commercial whale products will be banned. Would-be importers will have to apply for a licence not only for primary products but also for any goods (such as leather) which have been treated with a whale product. Denmark's insistence that

Greenland be excepted from this rule was accepted.

A recommendation obliging the nine member states to take steps to recycle waste paper and pulp was also adopted. Inks or glues which adversely affect the recycling process may fall victim should the legislation be seriously applied.

It was also agreed to finalize the Community's adherence both to the Strasbourg Convention (the Berne Convention) on the protection of European wildlife and their natural habitats and to the Geneva Convention on trans-frontier air pollution.

Jasper Becker

## High-energy physics

### New man, new style

The next director of DESY, the West German particle physics laboratory at Hamburg, will be 49-year-old Dr Volker Soergel, at present a member of the directorate of CERN, the European centre for particle physics in Geneva. Departing DESY director Professor Herwig Schopper announced the appointment during his leaving party at DESY last week.

Schopper moves to CERN in January as director-general; and Soergel will step into his shoes at DESY, even to the point of taking over his predecessor's professorship at the University of Hamburg. But from there on the similarities between the two individuals stop. Schopper had proved himself an extremely able politician in his period at DESY, but is less well known as a physicist; Soergel is a recognized expert on the weak decays of elementary particles, but has yet to learn the ways of Bonn.

However, he is by all accounts an extremely able administrator. According to one ex-CERN physicist, he could complete in ten minutes meetings that should have taken an hour — by resolving conflicts of interest beforehand. In this sense his style is ordered and Germanic. But at the same time, it is said, he can wax enthusiastic "and talk for hours about some harebrained scheme".

At DESY there are plenty of schemes, harebrained or not. A 30-beam synchrotron radiation laboratory opens in January; PETRA, the big electron-positron ring, is being pushed up to 22 GeV per beam in an attempt to find the elusive t-quark; superconducting magnets are being developed; and there are long-term plans for HERA, an 800-GeV proton on 35-GeV electron collider. But first, Soergel must find cash for DESY to pay its electricity bills (see *Nature* 4 December).

Being interested in the weak interaction, he will be keen to run PETRA at the energy where it can take data fastest on weak-electromagnetic interference, and check — in a hitherto impossible way — the Nobel-prize winning Weinberg-Salam unified theory of the weak and electromagnetic interactions. DESY physicists now

estimate that this requires experiments at 16 GeV per beam — not DESY's top energy, but enough to break the present budget if pursued for more than half 1981 running time. Given the cash, they say, they could have a result by May or June. It will be interesting to see if Professor Soergel can get it.

Robert Walgate

## Brazilian agriculture

### Soya beanfeast

Brasilia, November

In the scramble to develop its unexploited resources, officials say that Brazil is turning away from the Amazon Basin to an area of savannah, known locally as the Cerrados, covering about 180 million hectares mainly in the centre of the country. Attempts to open up the Cerrados, including the building of Brasilia, have so far produced only moderate results. But scientists have now convinced the government that the region offers great potential for agriculture.

The problem with savannah regions is that the very old soils have been leached of plant nutrients so only rough scrub supporting inefficient cattle grazing will grow. Aluminium concentrations in the Cerrados are also up to three times more than will be tolerated by most crops. Yet the soil structure and climate are good.

The problems of cultivation in the area are largely the responsibility of a government research institute, in the middle of the region, about 20 miles outside Brasilia. According to Dr Elmar Wagner, its scientific director, the aluminium and acidity problem can be solved by adding limestone, in quantities of roughly 2 tonnes per hectare depending on the crop to be grown. Fertility can be finally restored by adding approximately 150–180 kg of phosphate per hectare, and then maintained by the addition of nitrogen, phosphate, potassium, a trace of zinc and good soil and crop management.

Although Dr Wagner claims that agriculture can be maintained with less fertilizer than is commonly used in industrialized countries, fertilizing such a vast area would be a costly undertaking for Brazil, which has to import most of the raw materials for its fertilizer. So the search is

on for suitable nitrogen fixing crops.

Brazil has already experienced considerable success in breeding soya beans, now its main export crop, which fix all their nitrogen requirement. But attempts in 1979 to introduce nitrogen-fixing soya beans into the Cerrados from the southern coastal states were unsuccessful. Now a team at the Rural University of Rio de Janeiro claims to have discovered why.

According to Joanna Dobereiner, leader of the team, the sudden cultivation of newly-reclaimed tropical soils seems to increase *Streptomyces* fungi which produce antibiotics that kill off nitrogen fixing *Rhizobium* bacteria on the plants' roots. By isolating those strains of *Rhizobium* which survive and inoculating them into soya bean roots, she obtained good soya bean yields in a recent field trial in the Cerrados. She claims that by careful rotation of crops and by use of streptomycin-resistant *Rhizobium*, it may be possible to eliminate most of the need for artificial nitrogen fertilizer which accounts for 70 to 80 per cent of all fertilizer investment.

Most of the growth in farming in the Cerrados since 1975 has been in rough pasture for cattle raising. But Dr Wagner thinks that greater efficiency could be achieved by concentrating on grain crops and forestry. By cultivating most of the area available with improved methods he estimates that the total annual yield of grain crops could rise from 7.5 million tonnes now to 125 million tonnes and that of forestry from 15 million tonnes to 600 million tonnes. Meat production, he says, could be increased from 2.2 million tonnes annually now to 8.0 million tonnes even with pasture area reduced from 144 million to 80 million hectares.

With ambitious plans to cut oil imports further by using alcohol substitutes for petrol and vegetable oil substitutes for diesel, Brazil's need to open up more land to cultivation is becoming crucial. The problem was highlighted this year when Brazil was forced to import black beans from Mexico because some black bean land in the south had been turned over to alcohol production. The question now is whether the Cerrados could be used to grow food, leaving the traditional agricultural lands of the south free for sugar cane for alcohol, or whether the Cerrados itself could be turned over to sugar cane production.

Whatever the decision, the government will be faced with the problem of encouraging the growth of the Cerrados. It has been criticized in the past for encouraging the exploitation of land by wealthy southerners who seek quick profits and who have little interest in long-term development. A major challenge now will be transferring the results of research to the farmer and helping Brazil's underprivileged farming community in the north-east region to take part in the developments.

Judy Redfearn

## Schmitt stars again

Washington

Eight years ago he was collecting rock samples on the Moon. This summer he was a key fund-raiser for presidential candidate Ronald Reagan. And next year he will be the central figure for science in the US Senate, with responsibilities ranging from the programme of the National Aeronautics and Space Administration (NASA) to the budget of the National Institutes of Health (NIH).

A graduate from the California Institute of Technology with a PhD in geology from Harvard, Harrison (Jack) Schmitt won a surprise election victory as Senator for New Mexico in 1976.

Astronaut (right) and Senator (left) Schmitt

Last week he was appointed to head the Senate Commerce Committee's subcommittee on science technology and space. The committee is responsible for overseeing the programmes of both NASA and — if Senator Schmitt has his way — the National Science Foundation.

Not surprisingly, Senator Schmitt has been a keen supporter of the space research programme. With Senator Adlai Stevenson, the subcommittee's present chairman, he has been strongly critical of the Carter Administration's "unimaginative" approach to space policy — and his appointment has been welcomed in the space science community.

More controversial is his selection as chairman of the Senate's labour, health and human services subcommittee — responsible, among other things, for the biomedical research budget of NIH. This post was expected to go to Senator Charles Mathias, a liberal Republican and an enthusiast for biomedical research. But Senator Mathias has now shifted his attention to the Judiciary Committee, where he will counterbalance that committee's new chairman, conservative Senator Strom Thurmond.

Senator Schmitt's attitude towards this area of research is little known. Although a member of the present subcommittee, he has played little part in its deliberations on the NIH budget. As a geologist, he is expected to favour support for basic science; as an astronaut, NIH officials fear he may be drawn towards the high technology aspects of medical care, rather than its social and environmental dimensions.

David Dickson

## CORRESPONDENCE

## Nuclear cheap?

SIR—May I comment belatedly on Professor Jeffery's letter on nuclear costs (*Nature* 23 October, p.674). It is pointless trying to recalculate electricity generation costs on the basis of arbitrary rules. If, as Professor Jeffery believes, capital costs are inadequately reflected, does he propose to recalculate the current costs of coal and its transport in terms of capital expended in the nineteenth century? How does he propose to take account of the fact that if there had been no nuclear contribution the additional fossil fuel supplies would have had to come from expanded output at the marginal and most expensive sources? The costs published by the Central Electricity Generating Board (CEGB) for generation from Magnox nuclear stations and coal and oil fired power stations of similar age and load history, show that on a perfectly proper accountancy basis, including allowance for costs yet to be incurred, the price we would be paying for electricity would be higher now had fossil stations been preferred in the past.

The industry has stressed, however, that this alone is not a guide to future investment, any more than it would be if Magnox fuel costs increased more rapidly than coal and reversed the current cost position. Incidentally Professor Jeffery's projection of fossil fuel prices in terms of the sum of coal and oil prices compounds changes in fuel mix and offsets rising coal prices with the decline in real oil prices following the major price excursion in 1973. It conceals the 60 per cent real increase in coal prices which occurred between 1970 and 1979.

Fuel cycle costs for advanced gas-cooled reactors or pressurized water reactors are different from Magnox in that they refer to oxide fuels with higher burn up for reprocessing in THORP. Estimated future fuel costs are based in part on the expected cost of this plant. Electricity costs for stations yet to be constructed are calculated in constant money terms on a levelized cost basis by summing expected future discounted expenditures and dividing by expected discounted output. Our calculations, which may differ in detail from those of CEGB, suggest that even if coal costs were held steady and uranium prices allowed to rise (both contrary to present trends) nuclear should retain a small cost advantage.

P.M.S. JONES

UK Atomic Energy Authority,  
London SW1, UK

## Biospheric works

SIR—I have just read your article concerning Unesco in the 6 November issue of *Nature*. While I shall refrain from commenting upon the overall content of the article—although for instance we do not know here of any "new technological order" which would have been approved by the recent Belgrade session of our General Conference—there is one point in your text which particularly puzzles me. You state that our programme on Man and the Biosphere (MAB)—in which many scientists and institutions actively participate all over the world—is a source of "largely empty generalizations" and that "people and member governments increasingly ask whether it can be worth its cost".

A few years ago I outlined this programme to your readers in a lead article which appeared in *Nature* of 17th July 1975. The programme was still only emerging from its preparatory phase. It is now fully operational, with close to a thousand very concrete research projects under way in some 75 countries. Around 200 biosphere reserves have been established under the programme in 50 countries. Networks of integrated pilot research, training and demonstration projects have been set up in the humid tropics and in the arid grazing lands. Cities like Rome, Frankfurt or Mexico are being studied as urban systems under MAB. The annual cost of the programme to Unesco is approximately \$2 million only. This catalytic amount has attracted—mainly from industrialized countries—some \$50 millions of extra-budgetary support. In the aggregate it is estimated that national commitments to MAB run at about \$200 millions per year. It would indeed be strange that research organizations would spend such amounts for applied ecological studies leading only to empty generalizations. And everyone present at Belgrade can testify that the programme received enthusiastic support from all governments represented, whether developed or developing.

As a final point, let me indicate that MAB will be 10 years old this year and that we are organizing next October jointly with the International Council of Scientific Unions a conference-exhibit to review the progress of MAB, to evaluate its achievements and shortcomings and to make recommendations for its future. Any constructive criticism which *Nature* and its readers would wish to make would be most appreciated. But sweeping unsubstantiated statements are of no use in this context.

M. BATISSE

Unesco, Paris, France

## More on museums

SIR—May someone who is not by profession a scientist join in your controversy about "Museum pieces"? For like so many other non-scientists I do have a strong interest here, and that an interest of the kind which surely ought, in the present case, to be overriding. That is to say, I am a devoted museum goer myself, with children who also need the help of museums in their education. What we consumers of museum services are entitled to expect from our national institutions is a clear, vivid, fair and balanced presentation of all available materials. When there is fundamental disagreement on any issue of substance between the best qualified professional experts, then we are entitled to be told that such disagreement exists and what the main points at issue are.

Dr L.B. Halstead has made a very serious charge (*Nature* 20 November, p.208) that in the Natural History Museum the exhibits of dinosaurs and of fossil man are now presented in terms of a new theory which none of his critics has yet even suggested represents the consensus of the experts. Nor, it would appear, have those responsible for making up these exhibits and compiling the accompanying booklets done anything to explain and to stress that theirs is only one

view, and that probably a minority view, among those who are best qualified to judge. I would emphasize again that I make no pretensions whatsoever to any such special expertise. But it requires no expertise at all to recognize that Dr Halstead's charges are very serious indeed, and that none of the critics whose letters you have so far published has made any attempt to show that the situation is not in fact as scandalous as Dr Halstead's original letter suggested that it is.

ANTONY FLEW

Department of Philosophy,  
University of Reading, UK

SIR—In response to correspondence from L. B. Halstead (*Nature* 20 November, p. 208), I feel obligated to point out that while science is generally regarded as the outgrowth of processes of the cerebral cortex, Halstead's criticisms of cladistics seem to emanate more from the anterior pituitary.

First, although phylogenetic systematics (cladism) and the punctuated equilibria mode of evolution are largely complementary in their theoretical structure, at least one articulate spokesman for punctuated equilibrium is not a cladist, and therefore it is incorrect to lump the two schools together.

Next, although I am as firmly convinced of gradualism and evolutionary systematics as anyone, it is academic vigilantism to deny the cladists and punctuationalists their day in court. Those views are propounded by extremely competent scholars, whom I perceive to be fundamentally committed to the advancement of our understanding of the history and dynamic processes of life on Earth. This is a different goal (in fact, a directly opposite goal) from that of the creationists, and it is highly inappropriate for Halstead to analogize between their motives.

As for Halstead's innuendo that punctuational evolution is a Communist plot, I confess that I am never quite sure when British people are kidding, but I hope that Halstead was. Gould and Eldredge did spend one page of a thirty-five-page paper (*Paleobiology* 3, 115; 1977) relating their punctuational model of evolutionary change to the more general views of change espoused by Marx. Halstead's criticisms, however, do not address either the issues or the data; they instead take the form: (1) Marxism is wrong; (2) therefore, everything a Marxist says is wrong. This is obscurantism of a most pernicious sort, and side-steps the critical question of whether or not cladism or a punctuational mode of evolution has anything important to contribute to our understanding of the world.

When I see the maxillary and mandibular remains of the Miocene and Pliocene hominoids, I see (along with Halstead, I suspect) anagenesis, migration, allopatric speciation and gradual genetic divergence—without necessary recourse to a punctuational scheme. I do not see, however, how the vituperative essay of Halstead's sheds any new light on any relevant issues. Science should proceed through the critical analysis of ideas and explanations by recourse to the facts at hand: processes of logic and reason. Let us keep our hormones out of it.

University of Arizona, Tucson

## NEWS AND VIEWS

# Climate and variability in the solar constant

from Douglas Gough

AT one time or another almost every fluctuation in the Earth's climate has been attributed by someone to a variation in the solar constant. In many cases alternative, more convincing explanations have been found. For others there is mounting evidence that Milankovich's idea is correct: that variation in terrestrial insolation arising from changes in the elements of the Earth's motion is an important controlling factor. But there remain components of the climatic variation that are otherwise unexplained, and so it has recently become fashionable to study the implications of changes in the solar constant that arise from intrinsic variations in the solar energy flux. This has occurred partly because observational techniques now make it feasible to measure the small fluctuations that many meteorologists and climatologists believe to be sufficient to produce deviations in our weather.

At a recent workshop\* issues concerning the intrinsic variability of the Sun were discussed. The principal aim was to consider observations of the solar luminosity and radius, and to determine to what extent solar phenomena are correlated with changes in terrestrial climate.

The meeting began with a review by G. North (Goddard Space Flight Center) of climate modelling. This very difficult subject is still in a primitive state and any conclusions drawn from it must be viewed with caution. In 1973 the response of a rather sophisticated climate model (that devised by Tzvi Gal-Chen and S. Schneider at the National Center for Atmospheric Research) was investigated to see if a reduction in the solar constant of a few per cent would be sufficient to cause an ice age. The decrease was found not only to bring about an ice age but also produced a result that had not been anticipated: when the solar constant was restored to its original value, or even to a value somewhat higher, the ice would not melt. Astrophysicists believe firmly that the solar luminosity has evolved gradually during the past  $4.7 \times 10^9$  years from about 70 per cent of its present value, and thus the implication of that climatological experiment appeared to be that the Earth must always have been covered with ice. This is evidently not the

case. Therefore it seems inevitable that the climate model must be inadequate. Presumably the Earth has some stabilizing mechanism which operates only on a long time scale and which has not been taken into account. The Earth must be stable to the gradual evolutionary variation of the solar constant, but perhaps not to fluctuations on shorter time scales.

According to North, the situation has not changed since that experiment was performed. There have been various attempts to accommodate the evolutionary rise in the solar luminosity, by supposing the composition of the Earth's atmosphere to have changed such that the resultant variation in the atmospheric greenhouse effect cancelled the effect of the changing solar constant. But this variation has not been coupled either to the flux of incoming radiation, or to the state of the climate, so it appears to be quite accidental that the Sun and the Earth have kept in step. If one accepts that this is unlikely, one is left with what has recently been called the faint Sun paradox: either the astronomers are wrong or the climatologists are wrong; and if the latter is the case, either a long-term climatic stabilizing mechanism must exist or the climate is not really sensitive to changes in insolation on any time scale.

The evolutionary rise in the solar luminosity seems difficult to question, as A. Endal (Louisiana State University) emphasized. It is an apparently straightforward consequence of basic atomic and nuclear physics, gas kinetics and Newtonian gravitation. Therefore the astrophysical conclusion is robust. The sole caveat one might envisage is that perhaps the constant of gravitation ( $G$ ) is decreasing with time, as some cosmologists have suggested. The rate by which  $G$  must decrease to prevent a substantial variation in the solar constant is  $-G/G = 1 \times 10^{-11} \text{ y}^{-1}$ , which is below the present level of detectability. However, in the foreseeable future planetary ranging will no doubt enable measurements to be made.

On the other hand, the climatic balance appears to be rather delicate. A satisfactory self-contained theory does not exist, and the toy models, as North called them, rely on parameters which are determined from present-day empirical evidence and which are assumed to remain constant for all time. Evidently if the dependence of those parameters on the state of the climate were known and could be incorporated into the toy models, a drastic change in the stability

characteristics of those models could result.

To determine whether climate responds to small changes in the solar output, attempts have been made to correlate its variation with the solar cycle. This is a difficult task, since the response is only a small component of total climatic variation. Extensive work has been carried out by J.M. Mitchell, C.W. Stockton and D.M. Meko (in *Solar-terrestrial influences on weather and climate* p.125, eds McCormac, B.M. & Seliga, T.A., Reidel, Dordrecht, 1979), who have obtained an index of the average drought in the US since 1700 from tree-ring analysis. They have found a strong though imperfect correlation with the 22-year cycle, which agrees better with the actual sunspot record than with a regular oscillator with the same mean period. P.R. Bell (IEA) pointed out that an even better correlation exists between the drought record and a combination of the solar cycle and the lunar tides. The agreement is impressive, though its significance was challenged by Mitchell (NOAA, Silver Spring). According to M. Stuiver (University of Washington, Seattle) there is evidence for solar cycle variations in the  $^{14}\text{C}$  record, but there do not seem to be global climatic changes associated with the Maunder and Spörer minima (see *Nature* 286, 868; 1980).

Analyses of this kind have a bearing not only on climatology but also on the physics of solar variability. If an unambiguous relation between climate indices and certain aspects of solar variation could be established, it would be possible to attempt heliochronology from proxy records. Then one might be in a position to establish whether the solar cycle is regulated by an oscillation in which the entire Sun participates, or whether it is a phenomenon that is confined to the convection zone and its immediate environs.

A key to this problem may be the relative changes in the luminosity  $L$  and radius  $R$ , measured by the parameter  $W = \Delta \ln R / \Delta \ln L$ , where  $\Delta$  represents the small change associated with the cycle. It was agreed at the workshop that if the cycle were a purely superficial phenomenon, then  $W \approx 0$ . If, on the other hand, it is deep-seated, the magnitude of  $W$  is of

\*The workshop on solar constant variations was held at the Goddard Institute for Space Studies in Greenbelt, Maryland from 5 to 7 November, 1980. An extensive review of the meeting will be published by S. Sofia in due course.

Douglas Gough is in the Institute of Astronomy and the Department of Applied Mathematics and Theoretical Physics, University of Cambridge.

order (though rather less than) unity. Moreover, it appears that  $W > 0$  if surface variations result from perturbations throughout or at the base of the convection zone, as E.A. Spiegel and N.O. Weiss (*Nature* 287, 616; 1980), for example, have argued, and  $W < 0$  if the perturbing process is confined to the core, as R.H. Dicke (*New Scientist* 83, 12; 1979) upholds. Measurement of  $W$  is thus of great interest.

A whole day of the workshop was devoted to measurements of the solar constant. Rocket and balloon flights have not been frequent enough to gather much reliable information about trends, and ground-based observations have been plagued by interference from the Earth's atmosphere. In a critique of the day's proceedings, C. Fröhlich (Physikalisch-Meteorologisches Observatorium, Davos) concluded that the data were consistent with no variation, but that a secular decrease in  $L$  from 1966 at the rate of 0.1 per cent per decade is not ruled out. It must be appreciated that this apparent trend is merely the result of linear regression through data with large gaps. Recent measurements of visible and ultraviolet sunlight from the Nimbus and SMM satellites suggest a decrease in  $L$  at the rate of about 0.1 per cent per year since 1976, the year of the last sunspot minimum. If all the data are taken into consideration and the possibility of some observational inaccuracy is accepted, one might also see with an eye of faith the hint of a variation associated with the sunspot cycle, with amplitude a few tenths per cent and such that luminosity maxima occur at sunspot minima.

There is another interesting luminosity variation which has a lesser bearing on the main issues confronted at the workshop, and which was agreed by all concerned with the measurements to have occurred. This is an occasional decrease of order 0.1 per cent which persists for about 10 days. On the two occasions on which it has been observed there was a very large sunspot group on the solar disk. Thus it appears that sunspots can reduce the total heat flux through the photosphere for intervals comparable with the turnover time of the larger eddies in the convection zone. This indicates that the sunspot phenomenon is deep-seated, and not confined merely to the supergranular layers as some workers have maintained.

To complete the measurement of  $W$  one must obtain  $R$ . This might be inferred from the effective temperature via the black body radiation law, once the luminosity is known. Spiegel and Weiss (loc. cit) have used estimates of temperature variations made by W.C. Livingston (*Nature* 272, 340; 1978) from the CI 5380 spectrum line. However, Livingston (Kitt Peak Observatory) reported at the workshop that subsequent analyses of other lines, formed higher in the solar atmosphere, do not agree with the earlier conclusion. It appears that the atmospheric temperature

gradient has decreased between 1976 and 1980, but how this relates to the photospheric radius is unclear.

Direct measurements of the solar radius were discussed at some length. Most of this concerned trends on a time scale of centuries, which one might imagine to have been a relaxation from the Maunder minimum. There is a good deal of scatter in the data, and this no doubt has arisen in part from observational error. Eddy (High Altitude Observatory) reported a re-analysis of the Greenwich meridian circle data, and stands by his earlier conclusion (Eddy, J.A. & Boornazian, A.A. *Bull. Am. astr. Soc.* 11, 437; 1979) that the Sun appears to be shrinking, though the rate has been revised downwards. The estimate is now about 0.1 per cent per century, in rough agreement with the values reported by D. Dunham (Computer Science Corporation, Silver Spring) from eclipse analysis, and by B.J. LaBonte and R. Howard (Mount Wilson Observatory) from Mount Wilson photographs. It was noted that this disagrees with I. Shapiro's null result (*Science* 208, 51; 1980) obtained from Mercury transit measurements. Ancient transit measurements, like the Greenwich data, were dependent on observers' judgement, Eddy said, and it is hard to assess the accuracy of the results.

With this remark in mind it is perhaps not surprising that Parkinson *et al.* (*Nature* 288, 548; 1980) have concluded that Eddy and Boornazian's result is not a property of the Sun, but is simply a measure of the variation in not only the observers' opinions but also the seeing conditions and instrumentation. Parkinson *et al.* rediscuss the meridian circle measurements in this light, and also consider Mercury transit and solar eclipse data. They find no convincing evidence for a long term trend, though they do see the hint of a variation on a time scale of about 80 years. It has long been known that this is a time scale

associated with the sunspot cycle (Wolf, R. *Astron. Mitt. Zurich* 14, 1; 1862). It characterizes an irregular amplitude modulation of a kind common to a large class of nonlinear oscillators. It is not unlikely, therefore, that the seat of the modulation is intimately connected with the mechanism of the 22-year oscillation itself. Therefore the phase of the modulation relative to the radius variations is not without interest. Comparing figure 3 of Parkinson *et al.* with the sunspot data (for example, Waldmeier, M. *The sunspot-activity in the years 1610-1960* Schulthess, Zürich, 1961) suggests that maximum radius occurs at about the time when the amplitude of the sunspot cycle is at a minimum.

On a shorter time scale, LaBonte and Howard have deduced from Mount Wilson photoelectric measurements that a decrease in radius of about 0.01 per cent has occurred since 1974. During most of that time sunspot activity was increasing. T. Duvall (Goddard Space Flight Center) has made measurements of  $R$  using the vacuum tower at Kitt Peak National Observatory and H.A. Hill's (University of Arizona) finite Fourier transform definition of the solar limb. At the workshop he reported a decrease of  $0.02 \pm 0.02$  per cent since last December. Hill plans to improve the measurement, and hopes to achieve an accuracy of one part in  $10^7$ .

In summary, we cannot really be sure how either  $L$  or  $R$  is varying on time scales of decades or centuries. Measurements of radius variations over centuries are subject to a good deal of uncertainty, and direct luminosity measurements do not exist. But if one accepts the hints from the most recent observations, one may be tempted to infer that perhaps there are variations in  $L$  and  $R$  over the sunspot cycle, with maxima in both  $L$  and  $R$  occurring at sunspot minima. If that is indeed the case, then  $W > 0$ . □

## Development of spinal sensory systems

from T.M. Jessell and M. Yamamoto

CLASSICAL studies on the development of the spinal cord have focused on the motor neurone and its peripheral target, and the part played by synapse elimination and cell death in the modelling of connections<sup>1</sup>. Yet motor neurone death represents only the first in a series of changes which involve the elimination or reorganization of sensory and spinal neurones and which are

T. M. Jessell and M. Yamamoto are in the Department of Pharmacology, St. George's Hospital Medical School, University of London.

probably not completed until well after birth. Staining techniques that make it possible to trace individual afferent nerves have shown that sensory fibres that can be distinguished on the basis of their peripheral receptive properties also have unique and characteristic terminal arbors in the central nervous system. But how such specificity is generated is only just beginning to be understood.

In the developing rhesus monkey, for example, sensory fibres enter the dorsal horn of the spinal cord during the first

quarter of the gestational period and form well defined synaptic connections with cells occupying the most superficial border of the dorsal horn<sup>2</sup>. Three weeks later, however, these superficial neurones have degenerated, to be replaced by migrating cells that represent the future laminae I and II neurones. This loss of central targets may contribute to the degeneration of sensory neurones that is known to occur during normal development. But not all the sensory axons deprived of their post synaptic targets necessarily degenerate; others may survive to establish new and more stable synapses with superficial dorsal horn neurones<sup>2</sup>.

Moreover, remodelling is not only a question of the elimination and re-establishment of afferent and efferent connections; the spinal inter-neurones themselves undergo extensive morphological changes as they mature. In new-born mammals the neurones in the marginal zone and substantia gelatinosa have stubby, radial dendrites that lack any defined orientation. During the first two weeks after birth they shed some dendrites and elongate others to arrive at their final characteristic morphology<sup>3</sup>. The cues for neuronal elimination and dendritic reorganization in the dorsal horn are unknown and the contribution, if any, of afferent input may be difficult to determine. In the cerebellar cortex where similar problems have been examined in greater detail, the development of Purkinje cell dendrites appears to be partially dependent on intact climbing fibre or granule cell inputs<sup>4,5</sup> although even in the absence of presynaptic elements, a relatively elaborate dendritic arbor can still be generated.

These data raise interesting questions about the mechanisms by which the morphology of individual neurones is changed. At present, the only evidence bearing on this issue is ultrastructural. The additional membrane necessary for elongation of dendrites in the spinal cord, for example, seems to be generated by the fusion of vesicles with existing dendritic plasma membrane<sup>6</sup>; and degenerating spinal dendrites first become apparent as beaded processes containing numerous vesicles that eventually fuse to form cavities. Extraneous synapses on motor-neurones, on the other hand, seem to be removed by a rather more involved procedure. During the early post-natal period the number and distribution of synaptic terminals on motorneurones decreases by about 50 per cent<sup>7</sup>. In a series of beautiful ultrastructural studies, Ronnevi<sup>8</sup> has demonstrated that the phagocytosis of some synaptic terminals on motorneurones may be undertaken by the motorneurone itself. Motorneurone cell bodies can be seen to contain spherical presynaptic inclusions that have double-walled membranes and are packed with synaptic vesicles. The motorneurone is highly selective in the class of synaptic

terminal it engulfs, and other terminals are removed only by glial cells. Very similar double-walled vesicular structures have been noticed in embryonic mouse spinal cord<sup>9</sup> and in the immature cerebellar cortex<sup>10</sup> suggesting that this form of membrane remodelling may in fact be quite common in early development.

While investigations on the specific morphology and connectivity of sensory neurones have only relatively recently been attempted, it has not been until the past year that serious investigations on their specific chemical differentiation have become possible. The difficulty was that no sensory neurotransmitter had been identified, and the breakthrough has come with the discovery of substance P, somatostatin, cholecystokinin (or one of its shorter fragments) and vasoactive-intestinal polypeptide within small dorsal root ganglion neurones<sup>11</sup>. While it is still unclear what part these peptides may play in synaptic transmission or modulation, they have provided several new markers with which to examine the differentiation of sensory neurones. Kessler and Black<sup>12</sup> have shown that the substance P content of rat sensory neurones is markedly increased after post-natal administration of nerve growth factor (NGF), which is already known to be essential for the early development of dorsal root ganglion cells. Conversely, neonatal administration of anti-NGF antibodies depletes substance P from the cell bodies and terminals of immature sensory neurones<sup>13</sup>. Using rhodamine-conjugated NGF<sup>14</sup> it has been possible to show that NGF binds to receptors clustered at the tips of growing axons and is internalized and transported back towards the cell body of the neurone. Whether the internalized receptor complexes play any part in the actions of NGF on sensory neurones is, however, not yet known. Nor is it clear in these circumstances whether NGF is enhancing the survival of neurones already committed to the synthesis of substance P, or inducing substance P synthesis in neurones which would otherwise not have synthesized it. Two recent developments may make it

possible to answer this kind of question. First, there is evidence from experiments *in vitro* for two subpopulations of dorsal root ganglion neurones, only one of which depends for survival on NGF: the other will die in the presence of even a high concentration of NGF, but can be rescued by a factor derived from cultured glioma cells<sup>15,16</sup>. The generation of purified subpopulations of sensory neurones in culture on the basis of their growth-factor sensitivity may thus soon be feasible, and should help to resolve the question of whether the effects of NGF on peptide synthesis are due to selection or induction of cells.

The second important development is the discovery that 'factors' derived from non-neuronal cells can influence peptide synthesis by cultured sensory ganglion cells. Cultures of chick sensory neurones grown in the absence of other kinds of cells contain eight times as much substance P as somatostatin<sup>17</sup>. In the presence of ganglionic non-neuronal cells, the same number of neurones make six times as much somatostatin as substance P. This dramatic switch (analogous to the adrenergic-cholinergic switch reported for autonomic neurones *in vitro*<sup>18</sup>) can be reproduced by adding medium conditioned by non-neuronal cells to 'neurone-alone' cultures, but is independent of NGF-like material. This suggests that early in development a given sensory neurone may have the capacity to synthesize and store more than one peptide. Final determination of peptide expression is probably induced, by factors other than NGF, at a later stage, since somatostatin and substance P are present in separate populations of small dorsal root ganglion neurones in adult animals<sup>19</sup>. Cholecystokinin and vasoactive-intestinal polypeptide are also found in some sensory neurones so the choice open to a single neurone may be greater still.

In adult animals, peptides in sensory neurones have been assumed to function in synaptic transmission. They may however also have a trophic role during development, as has been suggested for the conventional neurotransmitters noradrenaline and 5-hydroxytryptamine. Destruction of noradrenergic neurones in the locus coeruleus of neonatal rats modifies the postnatal arborization of pyramidal cell dendrites in the neocortex<sup>20</sup> while inhibition of 5-hydroxytryptamine synthesis in embryonic rats delays the development of neurones in regions normally receiving a 5-hydroxytryptamine input<sup>21</sup>. Peptides released from immature sensory neurones as they grow into the spinal cord could then regulate the differentiation of surrounding neurones. The use of anti-NGF antibodies or capsaicin to deplete sensory neurones of substance P would provide one method of analysing the role of substance P and possible other peptides in the development of spinal neurones.

# Successes and failures in human *in vitro* fertilization

from Alexander Lopata

THREE infertile women have given birth to normal infants following *in vitro* fertilization (IVF) and embryo transfer (ET). In each of these women a single embryo had been implanted into the uterus during the early luteal phase of a natural menstrual cycle on one or several occasions<sup>1,2</sup>. Three other women conceived following ET but spontaneously aborted the fetus. One miscarried a 69XXX triploid fetus at 7 weeks gestation, a second miscarried an anatomically normal male fetus whose karyotype showed pleomorphism at 15D and a large Y chromosome at 21 weeks<sup>3</sup>, while the third miscarried a completely normal male fetus at 20 weeks following chorioamnionitis caused by an anaerobic Gram-negative bacillus.

The four pregnancies reported by Edwards and Steptoe<sup>1</sup> resulted from 32 embryo transfers and the two pregnancies reported by Lopata *et al.*<sup>2</sup> were obtained after 14 embryo transfers in 1979. After a number of changes were introduced in their laboratory the latter group carried out 10 additional embryo transfers by mid 1980 but have not obtained further pregnancies. Table 1 was compiled from the combined data and shows that at present the average efficiency of human embryo transfer is approximately 11 per cent whereas the probability of having a child following embryo transfer is three per cent. In contrast to this, live births have not yet occurred following transfer of one or more cultured embryos into the uterus of women whose ovaries had been stimulated with gonadotrophins or with Clomiphene citrate and hCG. Moreover, the efficiency of embryo transfer appears to be very low in these subjects since only three abortive pregnancies resulted from more than 77 embryos transferred by Edwards *et al.*<sup>1</sup> and biochemical evidence of early pregnancy was obtained in only three subjects

following 48 embryos implanted by the Melbourne group.

It should be noted that the computed success rate shown in Table 1 would be much lower if it were calculated on the basis of the total number of subjects monitored (treatment cycles) rather than on the basis of the number of embryo transfers carried out. Edwards and Steptoe monitored 78 menstrual cycles to obtain the 32 embryo transfers, whereas the Melbourne group monitored 69 subjects in 1979 and 63 in 1980. Thus, out of 210 women participating in the IVF and ET programmes, six became pregnant and of these, three delivered normal infants. The large wastage ensues from one of the following: failure to detect the distinct surge of luteinising hormone (LH) which is used for timing oocyte collection; ovulation occurring shortly before the ripe follicle is aspirated; the ovary containing the dominant follicle being inaccessible at laparoscopy; failure to recover an egg when the preovulatory follicle is aspirated; failure of fertilization or normal cleavage of the egg; failure of the embryo to establish pregnancy after it is transferred into the uterus.

Timing the collection of a preovulatory egg on the basis of 3-hourly urinary LH assays to detect the beginning of the gonadotrophin surge, which Edwards and Steptoe and the Melbourne group have used, is complicated by the following considerations. An oscillation in LH excretion is frequently detected before a distinct surge begins. The slope of the gonadotrophin surge and the peak value obtained may vary considerably between patients and often between menstrual cycles in the same patient. As these variations are inherent to the 3-hourly urinary LH assays, the criteria used to judge the start of the surge must be clearly defined to allow comparison of the time intervals (from start of surge to oocyte collection) selected by different groups of investigators.

Timing may begin from the baseline after the LH surge is detected, or from the mid-point of the first 3-hour interval when a sequential increase in LH begins, or from when the level of urinary LH excretion has increased by more than one, or two, standard deviations above the average baseline value. When timing began from the mid-point of the first 3-hour interval at which a sustained increase in urinary LH was detected, it was found that eggs recovered at 24 hours either failed to fertilize *in vitro* or underwent abnormal fertilization, whereas eggs recovered after 26, 28 and 30 hours yielded morphologically normal embryos. The two pregnancies reported by our group resulted from eggs collected 28 hours after the onset of the urinary LH surge. Steptoe *et al.*<sup>3</sup> have reported that their first two pregnancies resulted from eggs collected at 26 hours after the LH surge and the second two pregnancies from eggs aspirated after 24 hours. However, the criteria used for starting the timing of the interval for oocyte collection have not been defined by this latter group.

The time sequence of intrafollicular maturation of preovulatory eggs in women ovulating spontaneously needs to be further investigated. Using ultrasonic scanning of the preovulatory follicle, commencing at 27 hours after the onset of the LH surge and rescanning several times per hour until ovulation occurred, de Crespigny *et al.*<sup>4</sup> found that the interval from the start of the urinary LH surge to ovulation varied from less than 27 hours to 35 hours in nine women. Although this established that the time for follicular rupture varied by up to 8 hours between subjects it is now important to determine whether intrafollicular oocyte maturation requires a more constant time interval and is therefore independent of the actual time of ovulation. If, for example, preovulatory oocytes mature 24 hours after the LH rise, the follicle should be aspirated 25 to 26 hours after the onset of the surge to avoid spontaneous ovulation which occurs in about 20 per cent of subjects by 28 hours. On the other hand if meiotic maturity is incomplete, maturation of the egg in culture for several hours before insemination may improve results. Conversely, even brief periods of culture may be detrimental to mature human eggs, particularly if they resemble mature rabbit eggs which after 2 to 3 hours of ageing in culture remain fertilizable, but yield significantly fewer viable embryos<sup>5</sup>.

*In vitro* fertilization of human eggs has been reported to occur in modified Tyrode's solution formulated by Bavister<sup>6</sup>

Alexander Lopata is in the Department of Obstetrics and Gynaecology, University of Melbourne, and the Reproductive Biology Unit, Royal Women's Hospital, Carlton, Victoria, Australia.

and adapted by various investigators<sup>7,8,9</sup>, in media described by Biggers, Whitten and Whittingham<sup>10</sup>, and by Hoppe and Pitts<sup>11</sup> as well as in modified Ham's F10 medium<sup>2</sup>. Features common to these media include: a bicarbonate content which has been adjusted to maintain a pH between 7.4 and 7.6 in an atmosphere of 5 per cent CO<sub>2</sub>; an osmolality adjusted to between 280 and 285 mOsmol/kg; supplementation with either crystalline albumin (bovine or human), or with inactivated human serum, both of which are believed to favour *in vitro* capacitation and fertilization. Approximately 10<sup>6</sup> motile spermatozoa per ml of medium are frequently used for inseminating human eggs although concentrations ranging from 0.5 to 2.0 × 10<sup>6</sup> per ml have been employed. The duration of insemination, using washed spermatozoa, resulting in proven fertilization has ranged from 3 to 24 hours<sup>9,12</sup>. It is not known whether the conditions and media currently being used are optimal for human *in vitro* fertilization as adequately controlled experiments and statistical evaluations have not yet been reported.

Ham's F10 medium has been used most successfully for completing syngamy and initiating cleavage in fertilized human eggs, and for supporting development of the embryo up to the blastocyst stage<sup>13,14</sup>. This medium has been reported to be favourable for human preimplantation embryo growth at osmolalities ranging from 280 to 300 mOsmol per kg, and at pH levels from 7.2 to 7.4 in an atmosphere of 5% CO<sub>2</sub> + 5% O<sub>2</sub> + 90% N<sub>2</sub> at 37°C. As a general rule the medium is supplemented with either inactivated human serum, fetal calf serum or human cord serum, at levels ranging from 15 to 30 per cent. Other additions including antibiotics, glutamine, calcium, lactate, pyruvate and crystalline albumin may have been used yet these modifications are not reported in publications. Investigators tend to introduce changes in the culture media and in the procedures they use. The exact culture media used, the supplements added and their final concentration, the final pH and osmolality of the insemination and culture medium, and the duration of

incubation before fresh medium (if any) was introduced into the culture system, have not yet been sufficiently detailed by Edwards *et al.*<sup>1</sup> to enable others working in this area to duplicate the laboratory procedures which have resulted in the four pregnancies following IVF and ET.

Human embryos developed *in vitro* and transferred into the uterus through the cervix have a very low chance of establishing a pregnancy that will continue. The high wastage of transferred embryos may be due to defects in the embryo, endometrium, corpus luteum or the transfer procedure. A cleaving embryo placed in the uterus may fail to develop into a normal blastocyst or it may carry a chromosomal abnormality which causes its

early death. The luteal endometrium may become asynchronous with the stage of development of the embryo, or non-receptive as a result of the absence of humoral or hormonal factors released by the cultured embryo. An inadequately functioning corpus luteum may result from damage sustained by the follicle during oocyte aspiration, or its function may not be sustained due to the absence of an embryonic signal. Poor transfer technique may lead to damage of the embryo, or endometrium, or to failed retention of the embryo in the uterus. It is proposed that a systematic evaluation of all these factors is required before the next significant advance in human IVF and ET will be achieved.

## How heavy is a cold photon?

from N. Dombey

A welcome sign of the healthy state of theoretical physics today is the breakdown of the barriers which are insisted upon by grant-giving bodies and by most physics departments. Our research students in Britain, for example, must be strictly divided into astrophysicists (responsible to the SRC Astronomy, Space and Radio Board), nuclear or particle physicists (Nuclear Physics Board) and 'rest of physics' physicists (Science Board). But however useful (or useless) these divisions may be for experimentalists, they have been increasingly ignored by theorists over the last ten years or so.

The initial serious breakdown of these divisions came in the early 1970s as a result of Wilson's success with the application of renormalizable field theory to the classical problem of phase transitions; for the first time a sensible answer was provided to the question of why many critical indices are universal and independent of the substance undergoing the phase transition.

Many-body physics problems have for long been described in terms of thermodynamic, temperature-dependent Gibbs averages<sup>1</sup> rather than the zero-temperature vacuum expectation values of quantum field theory. It was also widely realised that a continuum limit of a crystal lattice system is applicable when the range of the excitations of interest is large compared with the lattice spacing as it is at a phase transition. But a systematic reduction of the different interactions of solid-state physics to the appropriate field theory came only with Wilson's work (see reference 2). Thus a Heisenberg ferromagnet can be reduced to the theory of an isovector scalar field  $\phi$  with an interaction  $|\phi|^2$  as for pions in particle physics. The critical exponents of the phase transitions can be calculated from the functions defined by the renormalization group equations of the field theory (for a

review see Kogut and Wilson<sup>3</sup>).

A phase transition represents a transition from one type of ordering or symmetry to another: in a ferromagnet, for example, all directions are equivalent above its transition temperature  $T_c$  (in the absence of an external magnetic field) so the system as a whole is rotationally invariant, but below  $T_c$  a ferromagnet will have a direction of magnetization which breaks this rotational symmetry. The interaction Hamiltonian which describes the behaviour of a ferromagnet for  $T < T_c$  as well as  $T > T_c$  is rotationally invariant — but the theory shows that the ground state of the system for  $T < T_c$  is one with the spins preferentially pointing in the same direction and thus does not satisfy rotational invariance. This is an example of 'spontaneous symmetry breaking' and it is characterized by the ground state not possessing the full symmetry of the interaction describing the system. Such theories have been studied now for many years both in solid-state theory (condensed-state theory is a better term to include superconductivity and superfluidity) and in particle theory where the Higgs mechanism of spontaneous symmetry breaking is used in analogy with the theory of superconductivity to generate mass. The best known case of this is the spontaneously broken unified gauge theory  $SU(2) \times U(1)$  of weak and electromagnetic interactions (*Nature* 282, 131; 1979) where the mass of the gauge particles  $W^\pm$ ,  $Z^0$  is generated in this way although in the underlying unbroken gauge theory they would have zero mass.

Thus a class of field theories with similar properties has been studied during the past ten years in both particle theory and condensed-state theory. The linkage with astrophysics and cosmology has more recently paralleled these studies, motivated in particular by the asymmetry of baryons (protons and neutrons) in the universe. According to the generally accepted big-bang theory the universe has been

N. Dombey is in the Department of Physics, University of Sussex.

expanding, and thereby cooling, from a state with infinite temperature and density, and the matter in the universe was created in the early stages of this process. Yet in spite of the law of baryon conservation, the universe contains large numbers of protons and neutrons, not anti-protons and anti-neutrons. Sakharov<sup>3</sup>, in a pioneering and far-sighted paper in 1967, tried to understand how this was possible. He assumed that baryon conservation was not absolute; so anti-protons could decay into electrons or negative muons (but then protons could also decay into  $e^+$  or  $\mu^+$ ). As it was known, however, that CP was violated by a small amount (C is charge conjugation which turns a particle into its anti-particle; P is parity inversion), the rates for proton and anti-proton decay could differ and hence a proton and electron predominance could be built up.

This was viewed as a wild speculation for many years. With the apparent successes of the unified  $SU(2) \times U(1)$  gauge theory of weak and electromagnetic interactions and of quantum chromodynamics (QCD — the  $SU(3)_c$  gauge theory of strong interactions *Nature* 279, 479; 1979), however, many theorists have in recent years considered grand unified gauge theories of which the simplest is the  $SU(5)$  theory of Georgi and Glashow<sup>4</sup> (see also this issue of *Nature* p. 649). This is a theory unifying strong, electromagnetic and weak interactions which is broken by the Higgs mechanism first into the unbroken  $SU(3)_c$  of strong interactions and the  $SU(2) \times U(1)$  of unified weak/electromagnetic interactions, which itself is then broken by the Higgs mechanism in the usual way. A common feature of the grand unified theories is that they contain gauge particles which couple baryons to leptons so that baryon conservation is no longer an exact law.

In order to estimate the size of baryon non-conservation, which would be reflected in a finite rather than infinite proton lifetime, it is necessary to calculate the masses of the gauge particles which mediate these processes. This can be done in the same way as for  $W^\pm$  and  $Z^0$  in  $SU(2) \times U(1)$ : the characteristic mass here is about 100 GeV which is the energy where weak interactions and electromagnetic interactions would have the same strength. Similarly the energy at which electromagnetic interactions become strong is about  $10^{15}$  GeV which therefore is the mass scale of these new particles. Thus the prediction of these theories is that baryons can decay into leptons but, as they would do so only by exchanging a superheavy gauge particle, this happens very rarely.

So there is a hierarchy of gauge theories

$$SU(5) \xrightarrow[100 \text{ GeV}]{10^{15} \text{ GeV}} SU(3)_c \times SU(2) \times U(1) \xrightarrow{\phantom{10^{15} \text{ GeV}}} SU(3)_c \times U(1)$$

where the fully symmetric  $SU(5)$  theory is only realised at energies large compared with  $10^{15}$  GeV so that the mass of all the gauge particles can be neglected; at

energies smaller than  $10^{15}$  GeV but much larger than 100 GeV the mass of  $W^\pm$  and  $Z^0$  can be neglected so that weak and electromagnetic interactions are fully unified; and in our normal low-energy region of laboratory experiments ( $< 100$  GeV) only QCD ( $SU(3)_c$ ) and QED ( $U(1)$ ) remain unbroken symmetries.

This is the present understanding of particle physicists who are eagerly waiting for an example of proton decay. Nevertheless, this hierarchy of gauge theories has immediate cosmological implications for the reasons advanced by Sakharov. We can consider the particles of these gauge theories as interacting with a background heat bath of temperature  $T$ . The appropriate theory would then be applicable to a very hot, very dense gas of particles interacting with the couplings of the gauge theory, provided that this gas had time to come to thermal equilibrium. So now Sakharov's speculation can be given flesh: at temperatures  $T > 10^{28}$  K corresponding to energies above  $10^{15}$  GeV this gas of radiation and particles will interact through a grand unified theory such as  $SU(5)$  with its 24 zero mass gauge particles, and baryons will be created which can then decay into leptons. As the temperature decreases, there is now the possibility of a phase transition of the gas into a new phase with lower symmetry: this has been studied and can indeed happen (see Linde<sup>5</sup> for a general review of the field). In particular, the present baryon-asymmetric state of the universe could be reached in this way, for a baryon asymmetry may have been produced in the early universe which was then 'frozen' in ever since<sup>6</sup>. So the hierarchy above can now be viewed schematically as

$$SU(5) \xrightarrow[10^{15} \text{ K}]{10^{28} \text{ K}} \begin{matrix} SU(3)_c \times SU(2) \times U(1) \\ SU(3)_c \times U(1) \end{matrix}$$

where the dense gas at temperatures above  $10^{28}$  K has the highest symmetry and various phase transitions occur to states of lower symmetry until we reach the present universe with its characteristic cosmic microwave temperature of 2.7 K at which only  $SU(3)_c$  and  $U(1)$  are good symmetries and of the original 24 gauge particles, only the 8 gluons of QCD and the photon of QED remain massless.

This brings us to the letter of Primack and Sher (p. 680, this issue of *Nature*): why they ask, should this hierarchy of broken gauge theories stop at  $SU(3)_c \times U(1)$  and  $T = 10^{15}$  K? Suppose at low enough

temperatures there is a further phase transition into a state of lower symmetry. This could imply "that the  $SU(3)$  gauge symmetry of the strong interactions, quantum chromodynamics, is broken at low temperature. Is it possible that the reason Fairbank and collaborators have been the only group to detect fractionally charged particles — quarks? — is that theirs is the only low temperature search?" This suggestion is due to Deshpande.

Alternatively, or additionally, there is an even more intriguing possibility. Perhaps the  $U(1)$  symmetry of QED is spontaneously broken. This would imply that its gauge particle, the photon, would become massive at a low enough temperature, or more exactly, that a photon gas in equilibrium with a heat bath would undergo a phase transition at  $T = T_c$  so that at temperatures below  $T_c$  each photon in the gas would have a non-zero mass  $\mu(T)$ . There would be various manifestations of a photon mass  $\mu$ . Following the review by Goldhaber and Nieto<sup>7</sup>, one can list four different effects and types of experiment:

- (i) the velocity of light would vary with its energy (that is, frequency)
- (ii) the electrostatic field would arise from a potential of Yukawa form ( $e^{-\mu r}$ ) rather than the  $1/r$  Coulomb potential. Here  $\hbar = c = 1$ .
- (iii) Ampère's law is violated and the corresponding Maxwell equation becomes  $\nabla \times H = J - \mu^2 A$  where  $A$  is the vector potential; this also leads to an exponential fall-off proportional to  $e^{-\mu r}$  of  $H$  for a magnetic dipole such as the earth, and
- (iv) the dispersion relation between frequency and wave-vector  $k$  becomes  $\omega^2 = k^2 + \mu^2$  in place of  $\omega^2 = k^2$ . This will give a change in arrival time of radio signals from a pulsar dependent on frequency. This can be accurately measured.

Each of these effects gives a bound on  $\mu$  with the best (precise measurements of the Earth's magnetic field) giving  $\mu \leq 3 \times 10^{-15}$  eV, and the others giving upper limits between  $10^{-10}$  and  $10^{-14}$  eV.

Primack and Sher note that all these experiments are performed either at normal temperatures ( $\sim 10^2$  K), or in the case of astronomical measurements, at 2.7 K. Thus they suggest that the photon mass be measured at temperatures much below 2.7 K. One such experiment is shortly to be performed at Sussex University by Clark and his collaborators. It will consist of looking for a frequency shift of a resonant mode in a superconducting cavity as the temperature is reduced in steps from an initial temperature of 4 K, where the photon is certainly massless, to a temperature of 0.05 K. It should be possible to measure the frequency shift (from (iv) above) arising from a phase transition giving the photon mass  $\mu$  to one part in  $10^8$ ; this should give a mass limit at these temperatures of about  $10^{-9}$  eV.  $\square$

## Selfish DNA

In two review articles in the 17 April issue Doolittle and Sapienza (p. 601) and Orgel and Crick (p. 604) separately suggested that much of the DNA in the genome of higher organisms could be described as 'selfish'. They argued that such DNA has no appreciable phenotypic effect and functions only to ensure its own self-preservation within the genome. This view point stimulated a great deal of comment, some of which was published in the issue of 26 June (p. 617). Now the original authors have joined up with one of their critics and reassessed their ideas in the two articles below. A further comment is added by H. K. Jain.

from L.E. Orgel, F.H.C. Crick and C. Sapienza

DIFFICULTIES have been caused by the words 'selfish', 'junk', 'specific' and 'phenotype' that were used in the two reviews of selfish DNA<sup>1,2</sup>.

Many people dislike the term 'selfish DNA' and a more acceptable alternative might be 'parasitic DNA'. The word 'parasitic' does not imply that the DNA can move between individuals, though certain viral DNAs might do this. It does imply that such DNA can usually move between different chromosomes in the same cell.

The word 'junk' also seems to arouse strong feelings. The idea behind it can be clarified by considering what is meant by 'specific'. We consider a sequence highly specific if the change of any one of its bases almost always has a considerable effect on the organism. An example would be the recognition site for a physiologically relevant restriction enzyme. At the other extreme are sequences whose deletion or extensive alteration would produce a negligible effect. Such sequences could reasonably be called junk. However, there is probably a continuum between these two extremes, including fairly specific sequences, where the alteration of most bases will produce some effect (many sequences coding for protein, and the different signals for starting and stopping transcription are likely to be of this type) and sequences whose deletion or extensive alteration will usually produce a small effect, such as a change in the local rate of recombination. In some cases close similarity of two sequences may be important, while the base sequences themselves may matter hardly at all — for example, within the introns of two neighbouring versions of a gene. The word 'junk' is perhaps too broad to cover all those cases for which the effect of sequence on the phenotype of an organism is small or zero. We hope a more precise terminology will evolve as the facts become better known.

The word 'phenotype' has also caused difficulties in spite of Doolittle and Sapienza's careful use of 'organismal

phenotype' to make their meaning clear. We obviously need two words: one to refer to the phenotype of the organism and the other to apply solely to the 'phenotype' of the parasitic DNA, a distinction we would certainly make in the case of a true parasite. For the former we would suggest 'organismal phenotype' and for the latter, following Cavalier-Smith<sup>3</sup>, 'intra-genomic phenotype', but we would allow the word 'phenotype' alone to be used when the context makes the meaning clear.

In our original definition we said that selfish DNA had two distinct properties: (1) It arises when a DNA sequence spreads by forming additional copies of itself within the genome. (2) It makes no specific contribution to the phenotype. By 'phenotype' we meant organismal phenotype. We intended 'specific' to be understood as 'highly specific' or 'fairly specific' in the discussion above. However it has been pointed out to us by R. Pritchard<sup>4</sup> that 'no... contribution' is unnecessarily strict. It would have been more useful to include also DNA which made a small contribution to the organismal phenotype, either positive or negative. An example of the latter might be a viral DNA which became part of the genome.

There is obviously a continuum of possible selective advantages (positive or negative) to the organism. We had excluded from our definition of selfish DNA those cases where the selective advantage is very high. To decide whether a repeated sequence is parasitic or not, one must determine whether the presence of the repeated sequence in the population is mainly due to the efficiency with which the sequence spreads intragenomically or mainly due to the reproductive success of those individuals in the population who possess repeated copies of the sequence. Only in the former case do we consider it useful to use the term selfish or parasitic DNA, as opposed to useful or symbiotic DNA — the borderline between the two may not be sharp.

In considering the spread of parasitic DNA one should not underestimate the power of natural selection. For example, if a particular transposon was inserted at

random, it would run the risk of inactivating many genes and thus be selected against. A transposon which usually inserted at sites between genes would be at a selective advantage. Sites very near essential genes (as pointed out by Bruce Grant<sup>5</sup>) may be harder to delete than those in the middle of long stretches of junk and so parasitic DNA in the former positions is likely to survive longer. Effects of this type would lead to the selection of selfish DNA sequences that inserted preferentially at special sites in the genome.

Competing theories differ in their analysis of the factors determining the amount of non-specific DNA and of the way in which it comes into existence. Although we cannot at present decide on the quantitative contribution of the different types of non-specific DNA to the genome, it is still helpful to classify the various theories.

We proposed<sup>2</sup> that the amount of non-specific DNA present in a given genome is often determined by the balance between the intragenomic spreading of selfish sequences and phenotypic selection against excess DNA — the weaker the phenotypic selection against non-specific DNA the larger the DNA content of the genome. In another group of theories it is proposed that there is an optimal DNA content for each organism, which may be substantially greater than the amount of specific DNA that is needed to define the phenotype. The amount of non-specific DNA is then principally determined by the difference between the optimal DNA content and the essential content of specific DNA. The theories are not mutually exclusive, but differ substantially in emphasis in their explanation of C-values.

Cavalier-Smith's proposal<sup>3,6</sup> is an interesting example of an 'optimal DNA content' theory. One of his ideas, which we misinterpreted in our previous paper<sup>2</sup>, is that in large cells, particularly in oocytes, the transport of messenger RNA across the nuclear membrane may become a limiting factor and that the only way to increase the

The "selfish DNA" design at the top of the page was created by Linda Angeloff-Sapienza of Halifax, Canada and originally appeared on the cover of the issue of 17 April, 1980.

L.E. Orgel and F.H.C. Crick are at The Salk Institute, San Diego, California and C. Sapienza is in the Department of Biochemistry, Dalhousie University, Halifax, Canada.

rate of transport is by increasing the number of nuclear pores by extending the surface of the membrane. If the area of nuclear membrane is determined by the DNA content of the nucleus, it follows that selection for a larger cell must lead to an increase in the DNA content of the genome. Thus, rather surprisingly, extra non-specific DNA is selected for because it allows such a cell to grow *faster*. While we do not question the logic of the argument, given the various assumptions, we do not find all the assumptions particularly plausible. It may be that there is sometimes selection for increased cell volume and increased nuclear volume. In cells so selected, non-specific DNA can accumulate. Whether it does so because large cells with large nuclei require such accumulation, or because they simply permit it remains to be seen. We feel that more experimental work is needed to unravel the complexities of the situation. In particular, we should like to know in which stages and in which organisms the surface of the nuclear membrane is saturated with nuclear pores.

Cavalier-Smith<sup>3</sup> also cites the widely different DNA contents of germ cells and somatic cells in some invertebrates as evidence against the selfish DNA hypothesis. However these observations can also be explained in terms of the selfish DNA theory. Such DNA 'needs' only to remain in the germ line to function parasitically. On the other hand, organismal selection might sometimes be stronger against surplus DNA in the soma than in the germ line. Thus representation in the germ line but not in the soma may sometimes be an optimal strategy for parasitic DNA. As for B chromosomes, in many cases the evidence appears to us to give some support to the idea (originally proposed by Östergren<sup>7</sup> in 1945) that they are largely parasitic, but there is certainly evidence that they sometimes have phenotypic effects which may possibly be useful<sup>8,9</sup>.

Smith<sup>10</sup> has pointed out that the DNA of vertebrates usually has about 42 per cent GC whereas the GC content of invertebrate and prokaryotic DNA varies over a much wider range. The theory of parasitic DNA has rather little to say on this point. There are many factors which might affect the GC content of an organism's DNA. If much of the parasitic DNA has descended rather recently from insertion elements which themselves originally coded for proteins, then it would not be surprising if their present GC content were similar to

that of genes which still code for protein. This may, perhaps, explain the constancy of GC in vertebrates.

As for our own ideas, we now feel that there may perhaps be reasons why too *little* DNA can in some cases produce a selective disadvantage. For example, Zuckerkandl<sup>11</sup> has suggested that there may be a minimum size for a 'domain' necessary for stability of the chromatin in the folded state. Thus a domain containing only a few genes might benefit from having some non-specific DNA as 'padding'. This would mean that there is indeed an optimal amount for total DNA.

In our original paper<sup>2</sup> we feel that we did not put enough emphasis on the distinction between sequences which are repeated, exactly or nearly exactly, in many tandem repetitions and sequences which are more widely dispersed over the chromosomes and which occur in only one or a few copies in any one place. It seems plausible that these two types of sequence evolved different mechanisms. It is possible that the mechanisms generating the tandemly repeated type are usually more 'ignorant' (in Dover's sense<sup>12</sup>) than the more dispersed type. If the latter have any specific function it is likely to be that of the control, at one level or another, of gene

expression, whereas the tandemly repeated type seem more likely to influence chromosome mechanics.

One possibility to which we feel we should have given more weight is that of 'dead genes', also called 'pseudo-genes'<sup>13,14</sup>; that is, sequences which can no longer code for a protein (or a structural RNA) but which appear to have descended from a sequence that did. Whether these conform to our definition of parasitic DNA remains to be seen, but we suspect this is unlikely, since they usually exist in only a single copy, or as multiple tandem copies in only one place.

In our recent experience most people will agree, after discussion, that ignorant DNA, parasitic DNA, symbiotic DNA (that is, parasitic DNA which has become useful to the organism) and 'dead' DNA of one sort or another are all likely to be present in the chromosomes of higher organisms. Where people differ is in their estimates of the relative amounts. We feel that this can only be decided by experiment. We expect that due to the recent advances in genetic engineering and related techniques much sequence information will accrue in the near future. This should help to decide between the different alternatives. □

## Modes of genome evolution

from Gabriel Dover and W. Ford Doolittle

OUR original articles<sup>1,3</sup> presented antagonistic positions and perhaps obscured many areas of agreement. In essence, we are approaching similar phenomena from different perspectives and it might be useful to clarify where our views agree and differ and to indicate the sorts of evidence which would allow one to decide whether the origin of non-coding DNA in eukaryotic cells is more precisely viewed as 'ignorant'<sup>3</sup> or 'selfish'<sup>1,2</sup>.

The eukaryotic genome is constantly in flux, and this plasticity results from a variety of known and as yet mysterious mechanisms which amplify and disperse segments of DNA throughout a set of chromosomes<sup>4-7</sup>. Replication and recombination are complex processes requiring many enzymes that have evolved by natural selection. What we both wish to stress is that, in establishing these processes, evolution has inadvertently endowed the genome with built-in mechanisms for irregular and recurrent random sequence rearrangements and

created an environment in which elements capable (to varying extents) of promoting their own amplification and dispersion will inevitably arise<sup>1,2,7</sup>. We acknowledge that there is evidence which suggests that some proportion of genome rearrangements may have effects on the biology of an organism (for instance on chromosome behaviour, on nuclear RNA processing, on cell-cycle times, on recombination frequencies and on gene expression; see refs 1-3, 8). Where this is the case, the change in frequency of a sequence rearrangement and the behaviour of elements which promote their own amplification and dispersion will of course depend on the effects they have on fitness. Hence, the net accumulation of these particular families of sequences reflects a balance between the intrinsic rate of accumulation (intra-genomically) and the effect of natural selection on phenotypic differences.

We agree that the amplification and dispersion of segments may occur either at random (sequence-independent or 'ignorant') or with preference for certain sequences (sequence-dependent or 'selfish'). Although both 'ignorant' and 'selfish' are unfortunate terms, they should be understood in the spirit in which they are

used and defined: sequence-independent and sequence-dependent processes of amplification and dispersion respectively.

The 'selfish process' produces DNAs which are preferentially chosen either by virtue of their nucleotide sequence or by virtue of the fact that they may code for gene products for their own amplification and dispersion. Mobile elements such as bacterial insertion sequences and transposons, the 'Ty-1-like' elements of yeast, the 'copia-like' elements of *Drosophila*, and vertebrate retroviruses, which show surprising similarities in structure and (perhaps) dispersal mechanisms<sup>8</sup> are almost certainly the self-perpetuating products of this sort of process. An alternative term 'self-selection' might usefully describe the process of accumulation of these sequences. Interestingly, there may be an element of self-selection in the process of accumulation and dispersion of some sequence-independent segments. Extensive sharing of similar sequence patterns of repetitive DNAs between chromosomes (see refs 9 and 10), and occasionally between species<sup>11,12</sup>, suggests that an arbitrarily accumulated sequence arrangement preferentially enjoys further rounds of amplification and dispersion<sup>10</sup>. Simulation of unequal recombination by computer appears to show a degree of self-perpetuation of sequences initially chosen at random<sup>13</sup> and also that amplification and dispersion can be part and parcel of the same recombinational irregularity<sup>14</sup>.

A process of recurrent amplification can explain the frequent observation of a greater within-species than between-species sequence homogeneity of shared families<sup>6,9,12</sup>. Similarly, polymorphisms and variations in sequence patterns of ribosomal genes<sup>15</sup>, histone genes<sup>16</sup> and some non-coding families<sup>17-19</sup> in several diverse organisms can be interpreted as the most recent, and hence localized, amplifications of these sequences.

We wish to emphasize, however, that 'ignorant' and 'selfish' self-perpetuation

are terms that uniquely apply to these particular DNA processes and cannot be used, meaningfully, to describe changes in frequencies of other elements that are totally dependent on the natural selection of phenotypes. 'Selfish genes'<sup>20</sup> and 'replicator selection'<sup>21</sup> are not synonymous terms and the evolutionary processes to which they allude are unknown. A very limited accumulation of supernumerary B chromosomes is the only other process that can be described as self-accumulation, often the result of meiotic and mitotic non-disjunction. We doubt if this term can be used to describe the mis-named 'meiotic drive' mechanisms of regular A chromosomes in the rare instances where this occurs. For example, in the case of segregation distortion (SD) in *Drosophila melanogaster*, the preferential recovery of the SD chromosome is not so much due to its accumulation *per se* but is the outcome of dysgenesis of cells carrying the non-SD homologue<sup>22</sup>. This, and other cases, are analogous to the relative changes in frequency of alleles at a gene locus that are the outcome of natural selection; and 'selfish' and 'replicator selection' are misleading descriptions of this process of differential accumulation of alleles and chromosomes.

We do not agree upon the relative contributions of randomly accumulated and preferentially accumulated DNAs to the evolution of eukaryote genomes. It is clear that much of the non-coding DNA of yeast could be of the sort one could call 'selfish'<sup>4,8</sup> whilst non-coding elements of the *D. melanogaster* genome are made up of varying proportions of essentially 'ignorant' repetitive DNA (for example the satellite DNAs<sup>23</sup>) and 'selfish' transposable DNAs (for example the 'copia-like' elements<sup>5</sup>). The scrambled arrangements of repetitive elements in *D. melanogaster* observed by Wensink and co-workers<sup>24</sup>

could reflect either sequence-independent shuffling processes or sequence-dependent insertion of transposable elements, similar to *copia*, at adjacent sites. The available data on repetitive DNA families of species of sea urchins, Gramineae, rodents, primates and insects (see ref.3) do not permit a clear assessment of the mechanisms that gave rise to them, for no direct sequence data are available. The multiple-copy 'Alu I' family of mammalian genomes may have a cellular function<sup>25,26</sup>, but it is not impossible that these are the descendants of a family of transposable elements<sup>27</sup>.

Finally, we suggest that the accumulation of sequences might be affected by constraints on the mechanisms themselves. For example, sequence-dependent amplification and dispersion will favour sequences that accurately contain the required sequence for transposition and that have not drifted too far into unacceptable divergent sequences. Similarly, sequence-independent mechanisms may be constrained to particular lengths of sequences<sup>10</sup>. Such constraints impose a type of selection on sequences, not necessarily as a result of their phenotypic effects but more as a consequence of the molecular mechanisms of replication and recombination.

We do not know what proportions of the repetitive DNAs of 'higher' organisms are amplified and dispersed by either sequence-dependent or sequence-independent mechanisms. Similarly, we do not know to what extent each of these mechanisms is constrained nor do we know the extent to which the frequencies of sequence patterns are an outcome of their possible effects on individual fitness. It is clear, however, that there are several modes of sequence rearrangement within rapidly evolving genomes. The problem now, as with most scientific debates, is one of quantification.

## Incidental DNA

from H.K. Jain

THERE can be two ways of looking at the extraordinarily large amounts of DNA in the eukaryotic genome. One is to keep looking for functions (mostly of a non-conventional nature, for example, determining nucleotypic effects<sup>1</sup>), and the other is to realise that lack of function is precisely what one would expect from a large part of the excess DNA. After all, the most important attributes one would expect of any kind of genetic material in the context of its fundamental role in evolution would be (a) mutability and recombination to create variation and (b)

mechanisms which would help to conserve a large part of this variation in spite of continuous selection, which leads to rejection of a great deal of newly-produced variability. Mechanisms of this kind are already known to exist. Heterozygote advantage is perhaps the most important of them. Ford<sup>2</sup> has argued on the basis of Fisher's<sup>3</sup> theory that heterozygote advantage has evolved because natural selection favours it as a major instrument for the preservation of variability and for keeping the population polymorphic.

Based on similar considerations, one would expect that the property of DNA to show mutability not only in the sense of classical gene mutations and chromosomal

rearrangements (for example, of the *Oenothera* kind) but also out-of-step fast replication (or amplification) of some parts of it is one which natural selection would help to evolve and fix in a population. Such a property may not be ascribed to quirks of DNA replication as suggested by Dover<sup>4</sup> but to selection favouring it. Natural selection is concerned not only with the existing variability but even more so with mechanisms which ensure its continued availability. If there is intragenomic selection leading to rapid build-up of some of the DNA sequences (the selfish DNA of Doolittle and Sapienza<sup>5</sup> and Orgel and Crick<sup>6</sup>) we must treat this part of DNA as *incidental* to the fundamental process of mutability so vital for ensuring continued supply of raw material for the production of new genes. It does not follow that all of the DNA produced in this manner will, in fact, acquire a function. A large part of it (or even all of it) may not do so and may be eliminated only on an evolutionary time scale. Meanwhile, new DNA of the same and similar kind may continue to be produced so that at a given point of time there will always be large amounts of non-specific DNA. This fraction is best described as 'incidental' rather than 'selfish' DNA. We may call it incidental because it is a byproduct of the inherent property of mutability of the genome, a characteristic to which natural selection attaches great importance even if it leads to the production of repeated sequences and a wasteful deployment of energy. Viewed in

this light, non-functional DNA is very much a product of natural selection — a selection operating for mutability *per se*. Its relative abundance is probably a function of its nonfunctional nature for any other DNA which carries information of one kind or another would create genetic imbalance and would be quickly rejected.

It is important to recognise that economy has not been a major consideration in the process of evolution. Overproduction and rejection (both quick and prolonged) are not uncommon features of evolution; the excessive amount of DNA should be considered in the same context. Nature places considerable premium on playing safe so that it will not run short of raw material even if this means indiscriminate production leading to sequences which are destined to remain functionless. With our present understanding of the origin of life (far from complete) and its evolution through

several billion years, we must be prepared by now to accept some degree of confusion. After all, the evolutionary process is without any kind of central management, planning and coordination. It is totally dependent on variability arising through errors in the replication of DNA and its subsequent multiplication through recombination, which at times may involve genome fusion<sup>7</sup>. Whatever control mechanisms do exist are themselves a product of these errors which have been seized upon by natural selection to bring about some amount of order. A large number of mutant genes are now known which affect the meiotic process in various ways including chromosome pairing<sup>8,9</sup>, chromosome condensation<sup>10</sup>, preferential segregation<sup>11</sup>, amount of recombination<sup>12,13</sup> and there are also, of course, the mutator genes<sup>14,15</sup>, some of which could possibly be involved in the production of non-specific DNA.

The use of the term 'selfish' may be quite harmless if one does not try to see too much meaning in it. With our recollection of the reactions to Darwin's theory, it is too much to expect that attempts of this kind will not be made. We do not have to be squeamish when science demolishes some of our cherished beliefs. The truth pointed out by Darwin has, in the end, given a more meaningful direction to our social and cultural evolution. By the same token, we do not have to create unnecessary despair if the interesting concept of selfish DNA is misunderstood, as is likely to happen.

### NEW GUINEA

from L.M. D'Alberty

"The most perfect harmony seems to reign in families of the Papuan Mahoris, and rare indeed are cases of quarrel among members of one household. They live in communities, sometimes of more than a thousand inhabitants, in well-built villages, worthy to be called small towns, both for their order and cleanliness. They are under the rule of the chiefs or landowners. The chief is looked upon as father of the family. He is called Pacao, and his servant or subject is called Irine. From all I could learn, slavery does not exist, and the sale of human beings is unknown." After describing their daily avocations, amusements, dress, implements, and ornaments (a group of which are figured), he goes on: "Their natural disposition is gentle and placid. They like to spend their time in talking and games, in which men and women take an equal share. Playful and free of speech,

*Durabi, a native of Kiwai Island, at the mouth of the Fly River*

they nevertheless do not transgress the bounds of modesty, either in word or deed. Women and children are included in every conversation, and often take part in public discussions, which are usually held in the evening. Women are always respected, and in some villages they enjoy a certain supremacy, although the government of the house belongs to the husband. Labour may

be said to be fairly divided between the two sexes, and they are accustomed to work from their earliest childhood. . . . Will they be the happier for civilization? This is a difficult problem, and one which cannot be solved until the experiment has been made. For my part I do not doubt that these, more readily than any other savages whom I know, would answer to the call of a civilised nation which, stretching out a paternal hand, would lead them towards our civilisation! To insure success, however, they should be treated as friends, not as slaves; they should be cherished, not destroyed."

Unfortunately our attempts at civilising savages have as yet in every case failed. Are we still, notwithstanding all our wretched failures, to go on in the old way, and allow these interesting and now happy people to be first ruined morally by the teaching of the dregs of our Australian and Pacific traders, and then physically deteriorated by the forced introduction of a form of civilisation utterly unsuited to them? Cannot either philanthropy, or religion, or Government protect these people from all such external influences as have been proved to be unsuited to their condition and stage of development, while aiding them to work out for themselves an indigenous civilisation? Here is perhaps the last chance we have to preserve one remnant of the better class of savages from being crushed under the juggernaut car of our high-pressure civilisation and mad struggle for wealth.

From *Nature* **23**, 23 December, 175, 1880.

## REVIEW ARTICLE

## Why unify?

Howard Georgi

Lyman Laboratory of Physics, Harvard University, Cambridge, Massachusetts 02138

*Unified gauge theories (such as  $SU(5)$ ) of particle interactions are built on the colour  $SU(3)$  and  $SU(2) \times U(1)$  gauge theories which apparently describe strong and weak and electromagnetic interactions at distances as small as  $10^{-16}$  cm. In this article the classical reasons for going beyond  $SU(3) \times SU(2) \times U(1)$  to a fully unified theory such as  $SU(5)$  are reviewed, and a new reason formulated. A class of imaginary worlds similar to our own is considered and it is shown that unification is possible only in ours. This suggests that the low-energy interactions are unique in that they are constructed to make unification possible.*

AS we enter the 1980s, elementary particle theorists have an unusual problem: we know (or think we know) too much. We confidently expect the standard  $SU(3) \times SU(2) \times U(1)$  gauge theory of the strong, weak and electromagnetic interactions to describe particle physics accurately down to distances as small as  $10^{-16}$  cm (ref. 1). The current status of particle physics has been reviewed by Mulvey<sup>2</sup>. This article also briefly discusses the symmetry groups such as  $SU(3)$ , used to describe elementary particles in terms of quark multiplets.

The  $SU(3)$  component of  $SU(3) \times SU(2) \times U(1)$  is the colour  $SU(3)$  theory of strong interactions or quantum chromodynamics (QCD) (the experimental and theoretical background which led to the development of QCD is reviewed in ref. 3). The eight  $SU(3)$  gauge particles are the gluons. They couple to the three colours of the quarks through the eight traceless, hermitian  $3 \times 3$  matrices. The effect of the colour  $SU(3)$  interactions is to confine the coloured quarks into colourless hadrons (for which all the  $SU(3)$  charges vanish).

The  $SU(2) \times U(1)$  component is the Glashow–Weinberg–Salam theory of the weak and electromagnetic interactions. The four  $SU(2) \times U(1)$  gauge particles are the  $W^\pm$  and  $Z^0$  (heavy because the  $SU(2) \times U(1)$  symmetry is spontaneously broken) and the photon.

There are still important questions in the 'low-energy' (<100 GeV) domain of contemporary particle experiments. For example, given the colour  $SU(3)$  theory, how, in detail, do quarks get confined? But the really fundamental questions seem to involve smaller distances and higher energies.

In 1973, it was suggested that the next step beyond  $SU(3) \times SU(2) \times U(1)$  must be the unification of these three gauge groups as subgroups of  $SU(5)$ , so that all of the low-energy particle forces are components of a single, basic force<sup>4</sup>. For a large class of models, including  $SU(5)$ , it was shown that unification must take place at very short distances of the order of  $10^{-29}$  cm (ref. 5).

But why should we go beyond the standard model at all? Here I review the obvious arguments for unification and suggest a new one.

### Experimental evidence

It is appropriate to begin with a few words about the quality of experimental support for the standard  $SU(3) \times SU(2) \times U(1)$  model. The evidence comes from many sources. There is much qualitative support for colour  $SU(3)$  in hadron spectroscopy and for  $SU(2) \times U(1)$  in the structure of weak decays. At a more quantitative level are lepton–lepton scattering and deep inelastic lepton–hadron scattering experiments. Summarizing this: although there is no single convincing datum (like  $g-2$  of the electron for QED), there are many strong indications all pointing in the same direction. Taken together, the evidence for  $SU(3) \times SU(2) \times U(1)$  is rather impressive.

Note that most of the quantitative support for  $SU(3) \times SU(2) \times U(1)$  was obtained after the  $SU(5)$  unification was proposed. Indeed, this is one of the main reasons that unification is taken more seriously now than when it was first suggested.

### Family structure

Intertwined with all the evidence for  $SU(3) \times SU(2) \times U(1)$  is the suggestive and mysterious family structure. Historically, the muon, its neutrino and the strange and charmed quarks were crucial in unravelling the structure of  $SU(3) \times SU(2) \times U(1)$ . But from a modern vantage point, they seem completely extraneous (and the  $\tau$  lepton and  $b$  quark even more so). We would be happy with a world in which only the electron, its neutrino and the up and down quarks exist. In fact, in discussing unification, I will consider only the electron family,  $e^-$ ,  $\nu_e$ , and  $u$  and  $d$ .

### $SU(5)$ unification

The left-handed (LH) fields transform as follows under  $SU(3) \times SU(2) \times U(1)$

$$\begin{aligned} (\nu_e, e^-)_L &: (1, 2)_{-1/2} \\ e_L^+ &: (1, 1)_1 \\ (u, d)_L &: (3, 2)_{1/6} \\ u_L^c &: (\bar{3}, 1)_{-2/3} \\ d_L^c &: (\bar{3}, 1)_{1/3} \end{aligned} \quad (1)$$

where  $c$  indicates charge conjugate; the two numbers in parentheses indicate the  $SU(3)$  and  $SU(2)$  representations (in that order) while the subscript is the  $U(1)$  quantum number (which is just the average electromagnetic charge of the multiplet); colour indices are suppressed.

In  $SU(5)$ , the  $(\nu_e, e^-)_L$  and  $d_L^c$  are combined into a five-dimensional representation of  $SU(5)$  which is conventionally called the  $\bar{5}$ . The corresponding right-handed (RH) fields,  $(e^+, \nu_e^c)_R$  and  $d_R$  thus transform like a  $5$ , the defining representation. The other LH fields transform like an irreducible 10-dimensional representation, the  $10$ .

In this simple structure, the total electromagnetic charge in each multiplet is zero as it must be. Furthermore, any  $SU(5)$  representation except a singlet must transform nontrivially under both the  $SU(2)$  and  $SU(3)$  subgroups, and these do. Finally, this system satisfies a nontrivial constraint, the absence of triangle anomalies, which must be satisfied for the theory to make sense<sup>6,7</sup>. This constraint can be described as follows: write the gauge group generators as matrices acting on the left-handed fermion fields. Then the symmetrized trace of any product of three generators must vanish. In particular, for any three diagonal generators, the product of the eigenvalues summed

over all the LH fermion states must be zero. This constraint is satisfied for the generators of the  $SU(3) \times SU(2) \times U(1)$  subgroup<sup>6-8</sup> and also for the rest of the  $SU(5)$  generators<sup>4</sup>.

## Charge quantization

$SU(5)$  provides a very simple explanation for the experimental fact of charge quantization. The fundamental 5 describes leptons with charges 1 and 0 and quarks with charge  $-1/3$ . Because all  $SU(5)$  representation can be built out of multiples of the 5, all charges are just sums of the fundamental charges and thus multiples of  $1/3$ . More than that there is a relation between colour  $SU(3)$  and charge because the fractional charge  $-1/3$  is carried only by the quarks in the 5. Thus triality zero states (and in particular colour singlet states) have integral charge. Triality one (two) states have charges  $n - 1/3$  ( $n + 1/3$ ) for integral  $n$ .

Given the specific charges in the 5, charge quantization is trivial because by inspection, all the charges in the 5 are commensurate. Actually the charge quantization theorem is deeper and it has a topological aspect. Whenever the unifying gauge group is compact, the charges have to come out commensurate<sup>4</sup>. This is also related to the fact that gauge theories based on simple groups have magnetic monopoles<sup>9</sup> which in turn are related to charge quantization.

## Coupling constant relations

The  $SU(5)$  scheme predicts a relation between the gauge couplings of the three subgroups, so that for example, it predicts  $\sin^2 \theta_w$  in terms of  $\alpha$  and  $\alpha_s$  (ref. 5). The quantitative prediction  $\sin^2 \theta_w \approx 0.205$  is in reasonable agreement with experiment. But, the picture of coupling constant renormalization in which all are equal at very small distances and evolve differently at larger distances gives a satisfying qualitative explanation of the hierarchy of particle interactions. It explains why the strong interactions are strong.

## Baryon number violations

The desire to explain charge quantization and to relate the different coupling constants motivated the search for unified theories from the beginning. Baryon number-violating interactions on the other hand were not sought after. Proton decay appeared unbidden in the  $SU(5)$  scheme and elsewhere<sup>10,11</sup>. But baryon number violation is now seen as an attractive artefact of unification. It yields the most plausible explanation yet proposed for the baryon number of the Universe<sup>12</sup>. Furthermore, current experiments should see proton decay directly and give us an entirely new view on the particle physics world<sup>13</sup>. Pati and Salam<sup>10</sup> have discussed baryon number violation in a partially unified theory. They have also considered<sup>11</sup> an alternative version of unification different from  $SU(5)$  and derived independently and at about the same time. They assume that the colour symmetry is spontaneously broken and the quarks are 'liberated' with integral charge. The baryon-number violation proceeds by a completely different mechanism (depending on colour breakdown) from that in the  $SU(5)$  model. In particular, it predicts baryon decay into final states with lepton number 3 rather than  $-1$ .

## Discussion

Besides these well known successes and predictions, the virtue of the  $SU(5)$  unification is its extreme economy and simplicity. However, this simplicity sometimes makes people suspicious. Can unification really be as simple as ' $2+3=5$ '? I believe that this simplicity is deceptive. The theory is not so much simple as unique. I shall now try to prove the uniqueness of  $SU(5)$  by discussing a class of imaginary worlds which cannot be unified.

First, I will argue that ' $2+2 \neq 4$ '. Consider a world like our own but with two colours instead of three. That is, the gauge group is  $SU(2) \times SU(2) \times U(1)$  and the LH fields are as follows:

$$\begin{aligned} (\nu_e, e^-)_L &: (1, 2)_{-1/2} \\ e_L^+ &: (1, 1)_1 \end{aligned} \quad (2a)$$

as in equation (1); the quarks have charges  $3/4$  and  $-1/4$ ,

$$\begin{aligned} (u, d)_L &: (2, 2)_{1/4} \\ u_L^c &: (2, 1)_{-3/4} \\ d_L^c &: (2, 1)_{1/4} \end{aligned} \quad (2b)$$

The charges of the quarks are determined by the constraint of anomaly cancellation for the  $SU(2) \times SU(2) \times U(1)$  theory.

Of course, this theory does not describe our world. We know that there are three colours and the quark charges are  $2/3$  and  $-1/3$ . But as far as we know, equation (2) describes a possible alternative world. Thus why is our world described by equation (1) rather than equation (2)? The only important difference is that the two-colour theory cannot be unified. This can be seen easily. The 11 fields of equation (2) cannot be divided into two subsets, each of which has total charge zero and is nontrivial with respect to  $SU(2) \times SU(2) \times U(1)$ . Thus any unification must treat all 11 fields as a single irreducible representation. But then the group must be  $SU(11)$  and the resulting theory does not satisfy the anomaly constraint.

Mathematically, we can describe the process of unification as follows: given a representation of a nonsimple group (such as  $SU(3) \times SU(2) \times U(1)$ ) which satisfies the anomaly constraint, find an anomaly-free simple extension (such as  $SU(5)$ ). As the example of  $SU(2) \times SU(2) \times U(1)$  shows, this is not always possible—in fact, it is usually not possible.

It is straightforward to show that in the same sense it is impossible to unify a theory of standard leptons and quarks with more than three colours. That is, we can consider an infinite class of imaginary worlds with gauge group  $SU(n) \times SU(2) \times U(1)$ ,  $n > 3$ , and LH fermions in a representation  $R$  (the quarks have charges  $(1 \pm n)/2n$ ):

$$\begin{aligned} (\nu_e, e^-)_L &: (1, 2)_{-1/2} \\ e_L^+ &: (1, 1)_1 \\ (u, d)_L &: (n, 2)_{1/2n} \\ u_L^c &: (\bar{n}, 1)_{-(n+1)/2n} \\ d_L^c &: (\bar{n}, 1)_{(n-1)/2n} \end{aligned} \quad (3)$$

Again, the charge is chosen to cancel the  $SU(n) \times SU(2) \times U(1)$  anomalies. Here, however, there is an argument against unification which does not involve the charge.

Assume that the unifying group is  $SU(N)$ ,  $N \geq n+2$ . This must be so because of the form of  $R$ . Only  $SU(N)$ ,  $0(4N+2)$  and  $E(6)$  have complex representations and the representations of  $0(4N+2)$  and  $E(6)$  contain other fields besides the leptons and 'quarks' of equation (3). Now consider some conventionally normalized colour generator  $T_c$ . In the representation  $R$  of equation (3),

$$\text{tr}(T_c^2)_R = 2 \quad (4)$$

by explicit calculation. But in the  $N$ -dimensional representation, this same trace satisfies the inequality

$$\text{tr}(T_c^2)_N \geq 1/2 \quad (5)$$

because the  $N$  must contain at least one  $n$  of the  $SU(n)$  subgroup. Now suppose that  $R \neq N$  (and  $R \neq \bar{N}$ ). We can derive a contradiction because the trace in any other representation is too large. It is easy to show that:

$$\frac{\text{tr}(T_c^2)_{R \neq N \text{ or } \bar{N}}}{\text{tr}(T_c^2)_N} \geq (N-2) \geq 4 \quad (6)$$

The first inequality is pure group theory. It is clear from the form of  $R$  that it cannot be a direct sum of more than one  $N$ . The next smallest representation is the  $N(N-1)/2$  which saturates the first inequality. The second inequality follows because  $N \geq$

$n + 2 \geq 6$  in the theories we are discussing. Comparing equations (4), (5) and (6) shows that  $R \neq N$  (or  $\bar{N}$ ) is impossible. Thus  $R$  must be the defining representation of  $SU(N)$ . This too is impossible because the theory has anomalies. The theory described by equation (3) for  $n > 3$  has no anomaly-free simple extension.

Of course, there are anomaly-free simple theories which contain  $SU(n) \times SU(2) \times U(1)$  for  $n \neq 3$ , but they must contain fermions beyond the usual quarks and leptons.  $SU(3) \times SU(2) \times$

$U(1)$  is unique in that it permits unification of quarks and leptons.

This article is based on a talk given at the 1980 Cosener's House conference on Grand Unification. I thank the Rutherford Labs and in particular Chris Maxwell, Gordon Ringland and Mike Teper, and the staff of the Cosener's House for their hospitality and encouragement. I thank Tony Zee for a correction to this work. This work was partly supported by NSF grant PH77-22864.

# Siderophile-enriched sediments from the Cretaceous-Tertiary boundary

Frank T. Kyte, Zhiming Zhou & John T. Wasson

Institute of Geophysics and Planetary Physics, University of California, Los Angeles, California 90024

*Siderophilic element concentrations are high in sediments from the Cretaceous-Tertiary boundary. An extraterrestrial source is indicated. Concentrations are too high to be understood in terms of the impact of a chondritic asteroid. Either the projectile was a metal-sulphide core or the infalling material (probably weak cometary matter) was slowed down during atmospheric passage.*

REPORTS by Alvarez *et al.*<sup>1,2</sup> of anomalously high Ir concentrations in Cretaceous-Tertiary (CT) boundary sediments led us to analyse samples from its most enriched boundary, the fish clay from Stevns Klint, Denmark, and a Pacific deep-sea drill core which crossed the CT boundary. Alvarez *et al.* interpret the high Ir content as characteristic of an asteroid having a radius of  $10 \pm 4$  km; they attribute the massive extinctions that marked the end of the Cretaceous to stratospheric opacity produced by impact-generated dust.

Because Ir is highly depleted in the Earth's crust relative to solar abundances, or the similar values in chondritic or iron meteorites, it is an ideal tracer for extraterrestrial sources. Other siderophiles (elements concentrated in an Fe-Ni phase if one is present) should also show high concentrations in the high Ir samples. Our procedure allows the rapid determination of several of these elements (Pd, Re, Os, Ir, Pt, Au) to compare their relative abundances in the CT boundary samples with those found in different groups of meteorites. Since starting this study there have been a similar but less comprehensive study of the Stevns Klint clay<sup>3</sup>, and data have been obtained on Ir, Os and several other elements in a boundary clay from Caravaca, Spain<sup>4</sup>.

## Samples

Analyses were performed on 23 samples of the Stevns Klint fish clay and three samples from Deep Sea Drilling Project (DSDP) Leg 62, hole 465A. The Danish specimens 1 and 2 had thicknesses of 3.5 and 2.5 cm respectively, and were sliced parallel to the pronounced bedding to measure variations in composition with stratigraphic position; these yielded 9 and 6 samples, respectively. Unfortunately, we may not have sampled the actual base because siderophiles and sulphide-associated

elements are highest in our lowest samples, whereas Christensen *et al.*<sup>5</sup> report a sharp decrease in concentrations of these elements in the basal, gray, layered marl. Eight specimens (numbers 4-11) which were dark coloured and clay-rich were also analysed; we infer that most of these originated in the lower portion of the section. Some have higher Ir concentrations than those determined in specimens 1 or 2.

Specimens 1 and 2 seem to contain three of the beds described by Christensen *et al.*<sup>5</sup>. In both specimens, sample 1 is the upper portion of a dark brown to grey marl, which must be either bed II or III. Both pairs of samples 2A and 2B are portions of a streaked grey marl corresponding to either bed III or IV. In sample 1, 3 this grades into the overlying lighter coloured marl which is certainly bed V. Here, the remaining samples are interbedded tan marls and fossiliferous chalk layers. The uncertainty in assigning the first two beds was due to: (1) the report<sup>5</sup> that bed IV is intermittent, and found only in the deepest portions of the depositional basins; and (2) that Christensen *et al.*'s bed IV is thicker (3-5 cm) than our second unit (6 mm)<sup>5</sup>.

DSDP hole 465A is located in the Central Pacific at  $33^\circ 49.23'N$  and  $178^\circ 55.14'E$ . Samples were taken from sections 3 and 4 in core 3. These sections primarily consist of a calcareous nannofossil-foraminifera ooze with the consistency of a thick paste; the Cretaceous-Tertiary boundary occurs within this ooze. The upper Cretaceous ooze is white and the lower Tertiary ooze is light tan. Unfortunately, drilling deformed the core and the boundary is smeared over at least 20 cm. Within this interval are several blebs of material containing pyrite (confirmed by our X-ray diffraction studies); these blebs may be fragments of a single 3-mm layer. We describe here the analysis of two samples containing pyrite (465A-1, 2), and one of the white ooze from below the boundary (465A-3).

## Experimental

All samples were dried at 150 °C for 24 h, then ground to a fine powder. Aliquots of 200–400 mg were irradiated with flux monitors at UCLA in a neutron flux of  $2 \times 10^{12} \text{ cm}^{-2} \text{ s}^{-1}$  for instrumental neutron activation analysis (INAA). Aliquots of 40–90 mg were leached with 1M HCl to determine  $\text{CaCO}_3$ .

Separate aliquots of ~1 g of six Stevns Klint samples were similarly irradiated for radiochemical neutron activation analysis (RNAA) of the elements Ir, Os, Pt, Re, Au, Pd, and Ge. After dissolution samples were fused in  $\text{Na}_2\text{O}_2$ , dissolved in HCl, and the noble siderophiles separated as a group on Sraffion resin<sup>6</sup>. Carrier recovery was determined by reactivation. Germanium was separated from the eluate by solvent extraction into  $\text{CCl}_4$  and purified by distillation as  $\text{GeCl}_4$ . The samples have high Br contents, and our determinations were seriously affected by neutron activated Br that was not easily eluted from the resin. The irradiated powders were therefore leached with  $\text{H}_2\text{O}$  before dissolution, reducing Br levels by a factor  $\geq 10$ . We doubt that this procedure removed a significant portion of the noble metals but confirmatory tests are in progress. Aliquots of Smithsonian standard Allende CV chondrite (split 3, pos. 18) were included in the RNAA runs as internal standards.

## Results

Table 1 shows INAA data for 25 elements and two  $\text{CaCO}_3$  determinations (the first based on loss on leaching with 1M HCl, the second based on the assumption that all Ca is present as  $\text{CaCO}_3$ ). The good agreement (67% within 6%) by these independent methods suggest that the latter assumption is correct, and that negligible amounts of other carbonates are present; and also that only a minor fraction of the Ca is in the clay. Table 2 lists the RNAA data for seven elements in six samples of the Danish fish clay. These data confirm the high concentrations of Ir and other siderophiles in the lowest strata. Correction for  $\text{CaCO}_3$  reduces the spread.

Our data on the Stevns Klint fish clay show good general agreement with those of Ganapathy; after allowing for anticipated sampling variations the only significant discrepancies seem to be our 3 times lower Re, 1.9 times higher Pt and 1.6 times lower Au values. Many of our data agree with those of Alvarez *et al.*<sup>1</sup> to within ~20%; we have compared their Stevns Klint samples with our basal samples 1, 1 and 2, 1 which have

similar Ir contents. The chief discrepancies are for a series of elements in which our values are lower by the listed factors: Co, 2.7; Ni, 2.1; Zn, 1.6; As, 2.4; Sb, 2.0. These elements are probably enhanced in strata with high pyrite content, thus the discrepancy can probably be attributed to sampling variations. Curiously, Se concentrations agree even though Se should also be enhanced in sulphide-rich samples.

Our data on DSDP hole 465A add another world location to CT boundaries having Ir concentrations far higher than typical values for pelagic clays<sup>7</sup>. Our Ir concentration of 16 ng per g is lower than those in the Stevns Klint and Caravaca boundary clays, but higher than that at Gubbio.

## Elements in the Stevns Klint fish clay

Relative INAA concentrations of 10 elements are plotted in Fig. 1 as a function of height within Stevns Klint fish clay section 1; all concentrations have been recalculated on a  $\text{CaCO}_3$ -free basis. Bulk  $\text{CaCO}_3$  concentrations are also shown for reference. Only elements whose corrected concentrations either decrease or are constant within 10% are plotted (most lithophiles are not plotted).

The fish clay is finely layered and the variations observed in the section are probably associated with changes in the mineralogy. Thus the very high contents of As, Se and Sb in the lowest sample (Fig. 1) probably reflect higher concentrations of sulphides. But whereas Se levels remain about 6–10 times lower in all higher samples, As and Sb pass through a minimum 4 times lower than the basal sample then rise to final concentrations higher than that in the basal sample. If these high As and Sb concentrations in the higher levels also reflect a high content of sulphides, these were either of a sort that did not enhance Se, or the Se source had decreased greatly before their formation.

More relevant to the present discussion is the behaviour of Ir, which is initially high, decreases by a factor of 2.6 at a height of 15 mm, then gradually rises again to 0.6–0.8 times the basal value. Similar patterns are shown by Fe, Co, and Ni. The trends of Zn and Cr differ from those of Ni and Co chiefly in that the basal values are not appreciably elevated relative to the higher samples. Bromine concentrations are very high in the three lowest samples, then fall rapidly to a plateau 2–3 times lower. As we can leach 90% of this Br with  $\text{H}_2\text{O}$ , it is only weakly bound.

**Table 1** Concentrations\* of 25 elements in the Stevns Klint fish clay and in samples from sections 3 and 4, core 3 of DSDP hole 465A, Leg 62 from the Central Pacific

\*Concentrations in  $\mu\text{g per g}$  except Fe, K, Ca and  $\text{CaCO}_3$ , mg per g, and Ir, ng per g.

†Midpoint heights are relative to the value assigned the lowest sample—see text.

Fig. 1 Abundance profiles for 10 elements in sample 1 from the Stevns Klint fish clay. Data are on a carbonate-free basis and normalized to give sample 1, 1 a value of 10. Only Se is severely depleted up the section and only Ir, As, Sb, and Br also are depleted significantly in most samples. In general, there is little difference between the base and top of the section.

Siderophile concentrations are high in all levels of the fish clay relative to those in normal pelagic clays. The fine lamination of the clay indicates an absence of bioturbation and that there must have been a rather continuous source of siderophile-rich material. The depositional environment here into shallow basins between mounds of Maastrichtian chalk<sup>5</sup>, might have favoured concentration of relatively dense mineral phases. Thus, if Ir is concentrated in such phases these depressions might have become traps for siderophile-rich materials whereas clay minerals were preferentially swept towards lower regions on the continental shelf.

### An extraterrestrial source of the siderophiles?

It has been suggested<sup>1,3,4</sup> that the worldwide enhancement in siderophiles in the CT boundary sediments resulted from the accretion of extraterrestrial material. Alvarez *et al.*<sup>1</sup> inferred an extraterrestrial origin of the Ir anomaly mainly because it is worldwide, coincides with the time of the Cretaceous extinctions, and because asteroidal impacts of the required magnitude should occur about every 100 Myr. They argued against reduction of Ir from the oceanic reservoir, or a worldwide reduction in pelagic sedimentation rates. Smit and Hertogen<sup>4</sup> accepted an extraterrestrial origin primarily because terrestrial sources appeared inadequate to account for the high Ir and Os at the boundary. Ganapathy<sup>3</sup> opted for an extraterrestrial source because common terrestrial rocks have very low siderophile concentrations, and relative abundance patterns in terrestrial rocks and ores are grossly different from the roughly chondritic pattern found in the Stevns Klint clay.

An important observation is that pyrite, FeS<sub>2</sub>, is a ubiquitous component of the CT boundary layers<sup>8</sup>. The formation of pyrite in marine sediments requires reducing conditions and high H<sub>2</sub>S concentrations<sup>9</sup>. In basins like the Norwegian-Danian Trough where the Stevns Klint fish clay formed, these conditions generally reflect the presence of stagnant water in closed basins.

How the required conditions are generated in the deep ocean, for example, at DSDP site 465, is not clear. As a trial hypothesis, we suggest that the reducing conditions are directly associated with the extinction of Cretaceous phytoplankton, and perhaps even resulted from the excess of dead organisms; reducing conditions may have been present in the oceans simultaneously throughout the world.

In fact, such reducing conditions may be necessary to avoid severe fractionation of extraterrestrial siderophiles before deposition. The oceanic residence time of an element is defined as the amount present divided by the steady-state injection or deposition rate. In present-day steady-state conditions, siderophile residence times vary by factors of at least 10<sup>3</sup>. For example, published<sup>10</sup> residence times are 0.20 kyr for Fe, 30 kyr for Co, 90 kyr for Ni and 120 kyr for Au. If these residence times are largely established by kinetic processes<sup>11</sup> such as ingestion by organisms, injection of large amounts of material having a solar Au/Fe ratio into the ocean would result in the first material to fall out having a Au/Fe ratio 600 times smaller than the solar ratio, whereas that in the sediments depositing a few kyr later would be much higher than the solar value.

Long residence times would have to be shortened to values comparable with the depositional periods of the CT sediments and reducing, high sulphide conditions offer plausible circumstances for this to occur. But if the residence times of siderophiles are reduced by a large factor, the deposition rate of oceanic siderophiles of terrestrial origin will be increased by a similar factor. Therefore, any deposition of relatively unfractionated extraterrestrial siderophiles is likely to be accompanied by an enhanced deposition of terrestrial siderophiles, the enhancement factor being roughly proportional to the steady-state oceanic residence time. This exacerbates the problem of separating the terrestrial and extraterrestrial signals.

Figure 2 shows our siderophile data for the six Stevns Klint samples studied by RNAA, and the INAA data available for the DSDP core 465A. In the upper portion element/Ni ratios are normalized to those in CI carbonaceous chondrites, in the lower portion to mean abundances in group IIAB iron meteorites. The following, very approximate, background concentrations based on intercepts on element-Ir diagrams were subtracted from the Stevns Klint samples: 10 mg per g Fe, 20 µg per g Co and 110 µg per g Ni. We had no basis for estimating background levels for the DSDP core. Elements are arranged in order of decreasing nebular condensation temperature<sup>12,13</sup>.

Table 2 Concentrations\* determined by RNAA of seven elements in the Stevns Klint fish clay

|         | Ir  | Os  | Re   | Pt    | Pd  | Au    | Ge    |
|---------|-----|-----|------|-------|-----|-------|-------|
| 4       | 42  | 32  | 9.7  | 60    | 44  | 5.9   | —     |
| 9       | 45  | 60  | 11.7 | 45    | 41  | 5.6   | 1.00  |
| 10      | 29  | 30  | 5.7  | 43    | 30  | 3.4   | 0.98  |
| Allende | 730 | 828 | 71.0 | 1,820 | 705 | 145.0 | 22.00 |
| 5       | 46  | 60  | 11.3 | 69    | 37  | 6.6   | 0.90  |
| 7       | 34  | 53  | 4.3  | 39    | 39  | 5.2   | 0.77  |
| 8       | 18  | 28  | 2.4  | 23    | 21  | 3.7   | 0.81  |
| Allende | 730 | 828 | 70.0 | 1,530 | 705 | 145.0 | 19.00 |

\*Concentrations in ng per g except Ge, µg per g. Each neutron activation run consisted of three clay samples and the Allende CV chondrite.

The Stevns Klint samples show significant fractionations relative to any known meteorites. Nickel-normalized abundances of Os and Ir are about 5 times higher than CI values; they are ~3 times higher than the highest chondritic abundances, those in CV chondrites. Although our Re/Ni ratios are about a third of those of Ganapathy<sup>3</sup>, our Re abundance ratios are still about double those for Os and Ir.

If Ni, our normalizing element, were 2.5–3 times higher, the pattern would be generally similar to that of CV chondrites. Although our inferred background Ni value of 110 µg per g may be too high, subtracting no background at all would only increase the average Ni concentration by a factor of ~1.6, much

less than required. Moreover, there are no unique background values that would generate constant ratios of other siderophiles to Ir. If a CI pattern were initially present, then some terrestrial fractionation has surely occurred.

The estimated mean composition of group IIAB iron meteorites shows an enrichment of refractory siderophile (Os, Ir) abundances by about 3 times relative to those in CI chondrites. As shown in Fig. 2b, normalizing to IIAB leads to mean abundance ratios closer to unity than does the CI normalization in Fig. 2a. This conflicts with Ganapathy's<sup>3</sup> inference that the impacting body was not an iron meteorite because 'most iron meteorites (with the exception of group I) show highly variable and noncosmic elemental ratios'. Ganapathy is right that individual, *m*-sized irons often show extreme fractionations associated with fractional crystallization. However, mean siderophile abundance patterns inferred by Willis<sup>14</sup> for entire cores are generally similar to those characteristic of chondrites.

**Fig. 2** Ni-normalized abundance ratios for nine siderophile elements plotted relative to a, CI and b IIAB. The six fish clay samples (●) from left to right are 5, 9, 7, 10, 4 and 8. Plot a shows the INAA data for Pacific core 465A-1 (left side) and 465A-2 (right side). Note that the fractionated patterns can be fit with both meteorite classes. The siderophiles Ge and Sb were not plotted because of the large amount of scatter introduced by correction for terrestrial materials.

A different fractionation pattern is observed in the Central Pacific sample 465A-1 (Fig. 2a). The abundance ratio of Ir is now 0.8, about 5 times lower than in the Stevns Klint clay; the Fe and especially the Co abundance ratios are even higher than in the Danish samples. Sample 465A-2 contained much less pyrite and siderophile abundances similar to the Stevns Klint sample. Perhaps the key message is that relative fractionation of siderophiles has occurred, and that the resulting patterns differ from location to location.

We can now consider whether the CT boundary siderophiles are of extraterrestrial origin. Significant fractions of some siderophiles are surely terrestrial, especially those that have relatively high oceanic residence times. The elements showing the highest abundance ratios in the Stevns Klint fish clay are Os and Ir. Alvarez *et al.*<sup>1</sup> report a concentration of Ir of  $< 4 \times 10^{-13}$  g per g in seawater that together with a mean ocean

depth of 3,700 m and a typical pelagic deposition rates of  $\sim 10^{-13}$  g Ir  $\text{cm}^{-2} \text{yr}^{-1}$  (ref. 7) suggest a residence time of  $\leq 10^6$  yr. It is important to establish this residence time or at least to lower the upper limit. If as seems likely the Ir residence time is comparable with or lower than the  $\sim 100$  kyr values of Ni and Au, the enhanced Ir/Au and Ir/Ni ratios in the CT boundary sediments require that most of the Ir be of extraterrestrial origin.

### An asteroidal impact?

Alvarez *et al.*<sup>1</sup>, Smit and Hertogen<sup>4</sup> and Ganapathy<sup>3</sup> interpret the high CT boundary siderophile contents as being caused by the impact of a large ( $\sim 10$  km) asteroid. Hsü<sup>15</sup> favours a cometary impact, based on the assumption that cometary ices will include chemicals toxic to phytoplankton. Comets apparently consist of roughly equal parts of ice and stony material<sup>16</sup>, thus the mass of impacting cometary material required to supply the observed accumulation of Ir would be twice that for a chondritic asteroid.

These hypotheses have serious problems in explaining the high Ir concentrations in the sediments. Table 3 lists maximum Ir concentrations observed in the four CT boundary sediments for which data are available. Because a negligible portion of the Ir is likely in the  $\text{CaCO}_3$ , the relevant data are those corrected for  $\text{CaCO}_3$ . The final column gives the extraterrestrial component (ETC), the ratio of Ir in the carbonate-free sediment to that in water-free CI chondrites<sup>17</sup>.

Alvarez *et al.*<sup>1</sup> quote the mass of impact ejecta as  $\sim 60$  times the mass of the projectile (R.A.F. Grieve unpublished). In fact, the ratio depends on the impact velocity (Grieve's estimate seems reasonable for  $\sim 20$  km  $\text{s}^{-1}$ ), and the size fraction of the ejecta and projectile material. In the fine fraction of ejecta taken near the rims of fresh lunar craters the ratio is far higher; 4.2 ng per g Ir (ref. 18) in the  $< 4$ - $\mu\text{m}$  fraction of immature soil 61220 (Table 3), implies a ratio of lunar to chondritic material of  $> 100$ . The two other lunar soils<sup>19</sup> listed in Table 3 are mature, that is, their siderophile contents have been enhanced by the continued accretion of projectiles that did not penetrate the regolithic debris layers on the lunar surface. However, we doubt that, following the hypothetical CT event, the ratio in the  $\leq 1$ - $\mu\text{m}$  size fraction having an appreciable stratospheric residence was much less than that in the fine fraction of soil 61220, although we cannot rule out this extreme fractionation.

Examination of the extraterrestrial components (ETC) listed in Table 3 shows that the Danish, Spanish and Central Pacific values are much higher than expected if the projectile had a chondritic composition and the ejecta/projectile ratio were 60. Further, the terrestrial component of the CT boundary sediments is unlikely to consist entirely of ejecta; if half consisted of non-ejecta detrital material, the anticipated ETC would be only  $\sim 0.8\%$ .

Our rare-earth data (Table 1) can be used to examine whether the CT boundary sediment had the same composition worldwide, as would be expected were it composed entirely of ejecta. In fact both the concentrations and the patterns are significantly different: relative to Stevns Klint, DSDP core 465A has half the La concentration, La/Ce ratios are  $\sim 3$  times higher, and La/Yb  $\sim 1.5$  times lower. The Danish sample resembles the average ocean sediment<sup>20</sup> as well as various continental volcanic rocks; the Ce depletion in the Pacific sediment is similar to but less pronounced than the depletion in ocean water. Alteration by interaction with the ocean water during sedimentation is unlikely, because the amount of La in 3 mm of our Pacific sediment exceeds by a factor of 13 that in the overlying 2.5 km of water. We conclude that a substantial non-ejecta contribution is present in one or both sediments.

We have shown that the siderophile pattern is consistent with the projectile being an iron meteorite. The siderophile content of a metal-sulphide core of an asteroid formed from relatively reduced chondritic materials such as H-group chondrites is about 3–4 times greater, that from more oxidized chondritic materials such as L chondrites  $\sim 6$ –7 times greater than those in

a chondritic projectile (a large fraction of all siderophiles except Fe enter the cores in both cases). If we neglect the high ETC of the Stevns Klint sample on the assumption that it reflects selective enrichment of ore minerals, and assume that the non-ejecta component of the other boundary sediments is  $\leq 0.5$ , a metallic core of an oxidized parent body might just account for Spanish and Pacific ETC values. About 20% of the fireballs observed by the Prairie Network enter the Earth's atmosphere at velocities  $\leq 15 \text{ km s}^{-1}$  (ref. 21); if the hypothetical CT object had such a low impact velocity the ejecta/projectile ratio might be  $\sim 30$ , half Grieves's value, and more in keeping with the high ETC values. Impact by interstellar comets or asteroids<sup>22</sup> would tend to result in impact velocities  $> 20 \text{ km s}^{-1}$ .

It is very unlikely that the siderophile enrichment in the CT boundary sediments resulted from the impact with the Earth's surface of a comet or of an asteroid having a chondritic composition. The data seem consistent with the impact of a metallic core, but only if the asteroid were relatively oxidized, the impact velocity were  $\leq 20 \text{ km s}^{-1}$  and if the non-ejecta fraction in the carbonate-free sediment were  $\leq 50\%$ .

### Extraterrestrial materials not impacting the Earth's surface

If the material accreted at the end of the Cretaceous were finely divided, it would be slowed to low velocities in the Earth's atmosphere. Because no ejecta would be produced, the high ETC values would not present a problem.

The most plausible source of finely divided material is an interstellar cloud. It is estimated that the Solar System encounters such clouds each time it passes through an arm of the Galaxy, roughly once each 100 Myr (refs 22–25). The amount of Ir that could be accreted depends on the cloud's density and size.

**Table 3** Maximum Ir concentrations\* observed in samples from the CT boundary at four worldwide locations and the finest fractions of three lunar soils<sup>14,15</sup>

| Location                  | Whole rock | Whole rock<br>-CaCO <sub>3</sub> | Extraterrestrial<br>components†<br>(%) |
|---------------------------|------------|----------------------------------|--|
| Denmark                   | 54         | 120                              | 21                                     |
| Italy                     | 5.5        | 9.1                              | 1.6                                    |
| Spain                     | 27         | 50                               | 9                                      |
| Central pacific           | 13         | 40                               | 7                                      |
| 15100 (<7 $\mu\text{m}$ ) | 19         | 19                               | 3                                      |
| 61200 (<4 $\mu\text{m}$ ) | 4.2        | 4.2                              | 0.7                                    |
| 66080 (<7 $\mu\text{m}$ ) | 22         | 22                               | 4                                      |

\*In ng per g.

†Extraterrestrial components (ETC) were obtained by dividing these concentrations by those in water-free CI chondrites (Ir = 580 ng per g).

A second-order effect is the dependence of the accretion rate on its vectorial velocity, the enhancement factor being approximately  $[1 + (V_{\text{esc}}^2/V_{\text{rel}}^2)]$  where  $V_{\text{rel}}$  is the relative velocity and  $V_{\text{esc}}$  is  $11.2 \text{ km s}^{-1}$ , the escape velocity from the Earth. The relative velocity is commonly estimated to be  $\sim 20 \text{ km s}^{-1}$ . If the velocity is in the range 20–40  $\text{km s}^{-1}$  and the vector is near the orbital plane of the earth, a significant enhancement could occur during some of the Earth's orbit, but the mean enhancement integrated around the orbit is not likely to be as large as a factor of 2. Gravitational focusing by the Sun would significantly enhance the solar accretion rate, but the enhancement of the terrestrial accretion rate would be much less. We will assume no enhancement.

Relative to Si =  $10^6$  atoms, the solar abundance of H is  $2.2 \times 10^{10}$  (ref. 26); our data on CI chondrites indicate an Ir abundance of 0.64. We will assume that these values are appropriate to interstellar clouds in our portion of the Galaxy. If the relative amount of terrestrial Ir was small at all locations, published data<sup>1,3,4</sup> indicate a mean worldwide accumulation

within the range  $8\text{--}80 \times 10^{-9} \text{ g cm}^{-2}$ . An accumulation of  $2 \times 10^{-8} \text{ g cm}^{-2}$  Ir could result from the passage of the Earth through a cloud having a mean density of  $10^5 \text{ H atoms cm}^{-3}$  and a diameter of  $8.6 \times 10^{19} \text{ cm}$  ( $= 5.7 \times 10^6 \text{ AU} = 28 \text{ pc}$ ), an order of magnitude greater than that estimated for the Orion 1 cloud<sup>27</sup>, one of the larger and denser interstellar clouds in our neighbourhood. Thus the probability of passage through such a dense region is probably considerably less than once each 100 Myr. Further, to account for the narrow Ir depth profiles in sediments such as that at Caravaca<sup>4</sup>, the bulk of the interstellar material needs to have been accreted from regions of exceptionally high density ( $\geq 10^6 \text{ H atoms cm}^{-3}$ ), or sedimentation rates must have been  $\leq 10^{-7} \text{ m yr}^{-1}$ , the lowest values observed in abyssal clays today.

Additional arguments against accretion of extrasolar material are a low <sup>244</sup>Pu content (<sup>244</sup>Pu/Ir ratio  $\leq 10^{-4}$ , see ref. 1) and the absence of measurable variations in <sup>191</sup>Ir/<sup>193</sup>Ir and <sup>184</sup>Os/<sup>190</sup>Os ratio<sup>1,3,4</sup>. However, studies of the Allende chondrite showed no variations in <sup>184</sup>Os/<sup>190</sup>Os either in the refractory inclusions having anomalous O isotope compositions or in chromite separates having isotopically anomalous Xe (ref. 28). The absence 4.5 Gyr ago of such variations in materials of diverse isotopic composition suggests that isotopic variations of Os and perhaps Ir as well may also have shown little variation in our part of the Galaxy 65 Myr ago. If the <sup>238</sup>U/Ir atom ratio in the interstellar cloud was equal to the solar value of about 0.03 present at the time the Solar System formed, the <sup>244</sup>Pu/<sup>238</sup>U ratio in the cloud was  $\leq 3 \times 10^{-3}$ , about 5 times lower than that initially present in the oldest meteorites<sup>29</sup>. The mean <sup>244</sup>Pu/<sup>238</sup>U surely varies by factors greater than 5 from cloud to cloud and possibly even within clouds, thus this discrepancy is not severe enough to require rejection of the interstellar cloud accretion model.

As an alternative to interstellar matter, material could enter the Earth's atmosphere as relatively large bodies but disintegrate because of low inherent strength, as thought to have occurred during the Tunguska event. De Laubenfels<sup>39</sup> first suggested that a Tunguska-like event could have triggered the Cretaceous extinctions. The Tunguska projectile was relatively small<sup>31</sup> depositing an energy of  $4 \pm 2 \times 10^{23} \text{ erg}$ , corresponding to  $2 \times 10^{11} \text{ g}$  if the velocity of  $20 \text{ km s}^{-1}$  is assumed. This is  $\sim 10^5$  times smaller than the amount of material inferred from Ir in the European or Pacific CT boundary sediments. The key question is whether in the  $\sim 5 \text{ s}$  atmospheric transit time a  $10^{17}\text{--}10^{18} \text{ g}$  object would break up completely. We doubt that it would and suggest that an object in a non-intersecting orbit broke up into a large number of smaller objects as it passed inside the Roche limit, with a portion of the debris entering new orbits that intersected the Earth's surface.

The Tunguska object has been interpreted as a cometary remnant. In fact, Kresak<sup>32</sup> associated it with Comet Encke. Many comets are structurally weak, as indicated by the fact that at least 10 have broken up without any apparent cause<sup>33,34</sup>. It seems plausible that such weak comets would undergo breakup inside the Roche limit.

About half the meteoritic material entering the Earth's atmosphere seems to be cometary<sup>21</sup>, suggesting that a super Tunguska event of the sort we describe is about as likely as the impact of an asteroid composed of tough materials, perhaps amounting to one event each 100 Myr. In contrast, passage through an interstellar cloud having the required column density would seem to be a far rarer event. We favour the super-Tunguska mechanism.

### Extinction mechanisms

Although infall of a comet may have marked the end of the Cretaceous, we are skeptical about Hsü's<sup>15</sup> marine extinction mechanism, poisoning by toxic cometary substances. Although HCN, CH<sub>3</sub>CN, and CO are certainly toxic for many organisms, the bulk of these would have been oxidized in the fireball that accompanied the cometary accretion. Further, such poisons

would not be selective among different planktonic species and would certainly have also had a deleterious effect on the benthic realm.

We suggest that cometary infall-related marine extinctions resulted either from thermal stress<sup>35,36</sup> or from the opacity of the stratosphere that would accompany the infall of  $10^6$ – $10^7$  times the mass of Tunguska<sup>1</sup>. Total darkness for a few days or a week would lead to the death of most phytoplankton, and a domino effect on the many organisms higher in the food chain.

We are also skeptical about the suggestion<sup>1</sup> that stratospheric opacity lasting for several years was responsible for the death of the dinosaurs and other large land animals. The estimate<sup>1</sup> of  $5 \times 10^{18}$  g of ejecta injected into the stratosphere corresponds to the total mass of the atmosphere above ~48 km, 10% of the atmosphere above ~31 km, and 1% above ~16 km. To keep such large amounts of material suspended, it would have to behave as elastically as gas molecules. In fact, it would probably stick on impact, the coagulation following second-order kinetics. For 2–3 years following the eruption of Krakatoa in 1883 its stratospheric dust produced a reddish-brown solar corona that could be seen in favourable conditions<sup>37</sup>. If favourable conditions were required to see the Krakatoa dust and if second-order kinetics controlled its fallout, clearly no matter how much dust you inject into the stratosphere, within a few months or less the level will drop to a value no more than a few times greater than that present immediately following the Krakatoa explosion. Stratospheric opacity could appreciably reduce photosynthesis by land plants for no more than one season, and probably a much shorter period.

It seems more likely that a major input of energy, whether by asteroidal impact or a super Tunguska, would lead to extensive destruction of forests by the blast wave and accompanying forest fires, as occurred within about a 100 km<sup>2</sup> area about the Tunguska epicentre<sup>38</sup>. Clearly no land animal larger than 25 kg (ref. 39) could have continued to survive in the scorched area near Tunguska.

Another extinction mechanism is required if the siderophiles were accreted from an interstellar cloud. In this case accretion to the solar surface would result in the conversion of gravitational energy to heat, with an increase in the luminosity, and extinctions due to thermal stress<sup>35,40</sup>. A cloud density of  $10^5$  H cm<sup>-3</sup> and a relative velocity of 20 km s<sup>-1</sup>, as used in our estimate, would increase the solar luminosity by 1% (ref. 41). Further, the increase depends on  $V_{rel}^3$ , thus a relative velocity about 25% lower would double the effect. One can easily imagine that as a result of the scatter in velocities and densities within a large interstellar cloud, there is a high probability that during short periods (say 100 yr) the solar luminosity would be increased by 20% or more, resulting in a mean increase in temperature of  $\geq 15$  K. Additional climatic effects are associated with solar

flares and distortions of the solar and terrestrial magnetic fields while the Solar System is immersed in an interstellar cloud<sup>24,25</sup>.

One interesting effect is the reduction of atmospheric O<sub>2</sub> as a result of the accretion of interstellar H<sub>2</sub> to the Earth (see also ref. 42). The estimated accumulation of Ir,  $2 \times 10^{-8}$  cm<sup>-2</sup> corresponds to 3.5 g cm<sup>-2</sup> of H, 14% of the amount required to fully convert atmospheric O<sub>2</sub> to H<sub>2</sub>O. In contrast to CO<sub>2</sub>, there is weak buffering on the atmospheric O<sub>2</sub> content; the level at any time represents a dynamic balance between photosynthetic production and various sinks; adjustment to shifts in the equilibrium abundance requires a few Myr (ref. 43). Baur and Friedl<sup>44</sup> recently suggested that early Mesozoic O<sub>2</sub> levels were only ~60% of present day levels. If levels in the Cretaceous 100 Myr later were also low, the impact of accretion of interstellar H could be still greater than the above estimates.

Undoubtedly many other effects deleterious to one or the other families of organisms would result from immersion of the Solar System in an interstellar cloud.

## Conclusions

A pyrite-bearing CT boundary clay from DSDP hole 465A in the Central Pacific has high concentrations of Ir and other siderophiles, confirming that the high siderophile contents found in shallower sediments are also found in those deposited at depths >2 km. Concentrations of 25 elements as a function of height in the finely layered CT boundary clay from Stevns Klint, Denmark show that although the highest concentrations are found in basal samples, carbonate-free concentrations of siderophiles are relatively high at all heights. The ubiquitous presence of pyrite in CT boundary sediments indicates extensive reducing conditions—these probably led to a reduction in the oceanic residence times and thus enhanced deposition for some terrestrial siderophiles. Nevertheless, we tentatively conclude that most of the Ir in the CT sediments is of extraterrestrial origin. Concentrations of Ir are higher than expected from the surficial impact of a comet or an asteroid of chondritic composition; a metal-sulphide asteroidal core is marginally possible, but it seems more likely that the siderophile-rich material reached terminal velocity in the atmosphere. There is a small possibility that this was dust from an interstellar cloud, but it is more probable that the near-Earth breakup of weak cometary materials produced a series of Tunguska-like events all around the globe.

We thank H. Tappan and A. R. Loeblich for discussions and for the Stevns Klint samples. The collection of the DSDP samples was supported by the NSF and L. Garifal and W. R. Riedel provided these samples. We thank F. Asaro, L. W. Alvarez, P. R. Weissman and J. Hertogen for helpful comments and J. Pai and A. Young for technical assistance.

Many examples of epigenetic metalliferous mineralization in central and northern England occur within a province now recognized to be characterized by high heat flow. Our analysis of this correlation leads us to conclude that Caledonian intrusive bodies, with high heat production and thermal conductivity, focused the development of hydrothermal systems responsible both for some types of post-Carboniferous mineralization and for present-day high heat flow.

TWO recent developments in the exploration for geothermal energy and metalliferous mineralization in Britain have highlighted a possible connection between the present-day heat production of rocks (due mainly to the long-lived isotopes  $^{238}\text{U}$ ,  $^{235}\text{U}$ ,  $^{232}\text{Th}$  and  $^{40}\text{K}$ ) and the distribution of epigenetic metalliferous mineralization dating from Hercynian and post-Hercynian times.

First, two high heat flow provinces characterized by surface heat flow  $> 60 \text{ mW m}^{-2}$  have been identified in Britain (Fig. 1a)<sup>1,2</sup>. The northern England high heat flow province (hereafter called the Province) extends as a southeasterly trending zone at least 100-km wide from southern Scotland across the Pennines through Yorkshire to the East Midlands; the south-west England province extends eastwards from Cornwall to Hampshire. Surface heat flow in these provinces is linearly correlated with heat production in crystalline rocks and low-grade metamorphic rocks of the pre-Variscan or Variscan basement, and the provinces show a strong spatial association with the known ore fields of the Lake District, the north and south Pennines (including Derbyshire) and Cornubia (Fig. 1b). Although the mineralized zone in the South Pennines lies on the western margin of the Province, various authors (see refs 3, 4) have indicated that the source of the mineralizing fluids lies to the east. Many occurrences of epigenetic mineralization may, therefore, be related to present-day zones of high heat flow and, where data are available, to above-average basement heat production<sup>5</sup>.

Second, it has become evident that the British granites which are associated with vein mineralization contain unusually high levels of heat-producing elements<sup>6</sup>. These granites seem to have influenced the circulation of hydrothermal fluids not only at the time of emplacement but also, by virtue of their high heat production and relatively high thermal conductivity, long after the period of their consolidation. For example, in south-west England, the Hercynian granites are associated with U-Sn-Pb mineralization, followed by Pb-Zn mineralization at lower temperatures, both dating roughly from the time of emplacement<sup>7</sup>; in addition, U mineralization seems to have continued into Tertiary times<sup>8</sup>. In northern England, where no granites younger than Caledonian are known, mineralization is often located in Carboniferous or post-Carboniferous rocks which post-date the initial cooling of the intrusions, but is known to be spatially related to intrusions under the Alston and Askrigg Blocks and in the Lake District. The model proposed here for the Province whereby hydrothermal convection is maintained by high heat production in granitic rocks has recently been proved quantitatively viable for the origin of uranium deposits in New Hampshire<sup>9</sup>.

Here we examine possible implications of these relationships which provide the basis for current geophysical and geochemical research being sponsored by NERC as part of the coordinated UK Deep Geology programme. Consideration is given to the processes of mineralization in the Province and to the possibility that concealed mineralization may be detectable.

**Fig. 1** *a*, Provinces of high heat flow in central and southern Britain; heat flow in the shaded areas exceeds  $60 \text{ mW m}^{-2}$  indicated by dashed lines in *b*, which also records the spatial occurrence of some important centres of hydrothermal mineralization in England and Wales (heat flow data from refs 2, 16, 22, 23, 31).

## Heat sources and mineralization

Regional geology suggests that the Province cannot be directly related to the distribution of any single stratigraphical unit in the pre-Permian basement (see ref. 2). Devonian and Carboniferous rocks, though present in some areas, are often thin or absent in the northwestern part of the Province. The sub-parallel alignment, on a regional scale, of the Province and the smooth linear anomalies of deep source shown on the 1:625,000 Aeromagnetic map<sup>10</sup> suggests a possible connection with pre-Carboniferous basement structure. Over much of its extent the Province is known to coincide with a Lower Palaeozoic basement-age province<sup>11</sup>; this correlation alone does not account for high heat flow which, instead, may be related to above-average heat production in granitic rocks and greenschist facies shale belts within the basement, both of which contain relatively high levels of radioelements.<sup>2,5,6</sup> The significance of these relationships is discussed below with reference to three principal areas.

(1) In the Lake District, there is a clear spatial relationship between Caledonian granites and later mineralization<sup>12-14</sup>. Average heat productivities in the Shap, Skiddaw and Eskdale granites ( $4.37 \mu\text{W m}^{-3}$ ,  $2.65 \mu\text{W m}^{-3}$ ,  $2.0 \mu\text{W m}^{-3}$ , respectively) are high compared with, for example, an average value of  $1.5 \mu\text{W m}^{-3}$  for Borrowdale volcanics<sup>15</sup> and a range of  $0.6$ – $2.0 \mu\text{W m}^{-3}$  for low-grade metasedimentary and metavolcanic rocks beneath England and Wales<sup>16</sup>. Recent studies<sup>17,18</sup> have shown that these intrusions are characterized by large negative Bouguer anomalies, indicating that large volumes of similar igneous rocks are present at a depth below the present erosion level. In geochemical and geophysical characteristics, these and other late Caledonian intrusions are comparable with the Hercynian plutons of the south-west England high heat flow province<sup>1,6,19</sup>. The relatively unfractionated heat-productivity profile of the Cornubian batholith in particular (requiring that the measured heat productivities are preserved to depths approaching 15 km (ref. 16)) might also apply in the Caledonian plutons. This suggestion is consistent with mineralogical studies<sup>20</sup> indicating that, away from areas of mineralization, uranium in both the Cornubian and late Caledonian granites is held in primary mineral phases. By virtue of their high heat production and thermal conductivity, Caledonian granites beneath the Province would not only have added heat to fuel convective systems involving formation waters in Lower Carboniferous and older sediments beneath thick sedimentary cover<sup>21</sup>, but they might also have continued to act as significant conductive heat-transfer agents during later periods. A mean thermal conductivity of  $3.3 \text{ W m}^{-1} \text{ K}^{-1}$  for comparable Cornubian granites<sup>22</sup> is much higher, for example, than a typical value of  $1.5 \text{ W m}^{-1} \text{ K}^{-1}$  for shale horizons<sup>23</sup>. In some circumstances where upward deformation of sediments has occurred around granites, heat may have been refracted towards those granites (for details, see ref. 5).

(2) Well documented areas<sup>24,25</sup> of epigenetic mineralization above buried Caledonian granites occur in the north Pennines (Fig. 1) at Weardale and Wensleydale. For example, the Rookhope borehole, drilled to investigate the coincidence of the centre of a zonal pattern of Pb–Zn–fluorite–barite mineralization in Carboniferous rocks<sup>26,27</sup> and areas of strong negative Bouguer anomaly<sup>28</sup>, proved the presence of the Caledonian-aged Weardale granite<sup>24</sup>. Whether mineralization in the north Pennine orefield occurred during a single short-lived episode<sup>29</sup> or in repeated episodes<sup>30</sup>, it certainly took place long after these ~400-Myr-old granites had crystallized: a possible link to radioactive heat production is implied. A geothermal gradient of  $31^\circ\text{C km}^{-1}$  at Weardale<sup>31</sup> supports comparisons of the thermal properties of this granite with those of the Cornubian batholith where gradients of  $27$ – $35^\circ\text{C km}^{-1}$  are typical<sup>22</sup>. If the model for mineralization developed for south-west England (ref. 6 and above) is applied to late Caledonian granites, particularly those which are covered by sediments, it follows that concealed mineralization may exist elsewhere in buried sediments which are younger than the granites and with which there would be a close spatial relationship.

(3) The south Pennine–East Midlands section of the Province (Fig. 1) contains the vein and stratiform Pb–Zn–fluorite mineralization of Derbyshire which occupies a tract with NNW elongation. Ford<sup>4</sup> postulated a migration of brines from the North Sea basin to account for the availability of mineralizing fluids in the area. This interpretation, however, (see ref. 32) involves the proposals that the fluids travelled some 150 km up-dip in Carboniferous strata without significant heat loss and that they crossed the Askern structural high<sup>33</sup>. Such difficulties focus attention on the possible influence of local heat sources and, by comparison with the north Pennines, Evans and Maroof<sup>34</sup> suggested that there may be Caledonian intrusive rocks beneath the East Midlands and that these might have exerted an important control. Unfortunately, present geophysical data are equivocal in respect of the presence or absence of buried granite bodies in the south Pennine–East Midlands region. The available deep boreholes penetrate pre-Carboniferous shales with moderate heat production (our unpublished data) and do not reach crystalline basement. Although there is no clear explanation for above-average heat flow in the south-west quadrant of the Province we postulate, by analogy with the Lake District–North Pennine areas, that high basement heat flow related to granites may be responsible: the geophysical implications of this suggestion are receiving further attention. However, we note that water circulating through and rising from deep aquifers beneath horizons of low thermal conductivity provides a more attractive explanation for high heat flow in some parts of the Province, such as east Lincolnshire and Yorkshire, which are underlain by deep sedimentary basins.

## Prerequisites for Pennine mineralization

Epigenetic Pb–Zn vein-type and strata-bound ores of the Mississippi Valley type are characteristically of low-temperature hydrothermal origin<sup>35,36</sup> and, as such, their formation requires slightly elevated thermal gradients, trapped halogen-rich aqueous fluids in permeable rocks and preferably a structural anomaly, such as a fault zone or fractured anticline, to promote fluid circulation. Fluid circulation is also favoured by sources of magmatic or tectonic heat, but these are not essential prerequisites. In the case of Pennine mineralization, it is generally agreed that Lower Carboniferous limestones and sandstones contained the trapped connate water but that the source of base metals was either within Lower Carboniferous shales or within earlier Palaeozoic metasediments<sup>4,30,32,34</sup>. The metals were leached by hydrothermal brines which, from fluid-inclusion studies<sup>32</sup>, are known to have had high salinities and temperatures (~200°C). Some  $^{34}\text{S}/^{32}\text{S}$  ratios for galena<sup>37</sup> and, in particular, the quantity and the rare-earth element geochemistry of fluorite in Pennine mineralization have both been taken to indicate, however, that the genesis of these deposits could have been related to magmatic sources<sup>38</sup>.

An important point of contrast between the Pennine deposits and those of both the Mississippi Valley and the Irish Pb–Zn deposits within Lower Carboniferous host rocks<sup>40,41</sup> is that whereas the latter occurrences are fault-controlled<sup>39</sup>, the Pennine deposits are spatially related to domes. In view of the age discrepancy mentioned earlier, this may be taken as evidence that the role of older Caledonian granites was not only to act as channelways for mineralizing fluids<sup>30</sup>, but that they may have been heat-focusing agents. Flow of fluorine-rich fluids through these granites may have remobilized base metals during hydrothermal processes and may have led to continued enrichment. Differences between the sulphide assemblages of the two Pennine areas suggest a higher temperature regime in the northern (Alston) region<sup>42,43</sup>, a feature which correlates with recent data<sup>5</sup> on the differences in heat flow from the two blocks. In addition to possible contributions from heat-focusing granites, the flow of mineralizing fluids was controlled by faults<sup>44</sup> formed during differential uplift at the end of the Carboniferous, resulting in the deposition of ores at intersections with favourable sedimentary horizons.

## Implications for mineral exploration

The present model is that metalliferous minerals were concentrated magmatically during a Caledonian phase and may have been redeposited in mineral veins near the contemporaneous land surface or on or just beneath a shallow sea floor if later phases of mineralization took place. The process could have continued as long as hydrothermal systems were able to circulate against the hydrostatic gradient, possibly into Tertiary times. The search for minerals should, therefore, be concentrated at and below ancient land or sea-bottom surfaces. Several lines of evidence, including studies of metamorphic facies<sup>16</sup> and levels of granite intrusions<sup>43</sup>, suggest that the present land surface of the northern end of the Province is close to that present at the end of the Devonian. If hydrothermal circulation is able to reach near-surface conditions<sup>6,7</sup>, it follows that most epigenetic mineralization associated with areas that have been positive blocks during post-Devonian time must crop out at, or near, the surface and may be found by established methods of geochemical and geophysical exploration<sup>46,47</sup>. Sedimentary basins containing Carboniferous and later strata, such as those which occupy the central and southeastern part of the Province, may contain deposits at greater depths.

Comparisons with the known history of mineralization in the south-west England high heat flow province (particularly Cornwall, Fig. 1) suggests that the possible existence of two other types of deeply buried deposit in the northern Province is worth consideration. First, in Cornwall, where there is evidence of several post-Hercynian episodes of U remobilization analogous to those discussed above, Sn-W mineralization seems to

have been related only to a high-temperature event closely linked with magmatism. Metals which were not remobilized by low-temperature hydrothermal processes may remain in similarly close association with buried Caledonian granites. Second, stratiform metalliferous deposits in Carboniferous and Permian strata may exist beneath the cratonic cover of Jurassic or younger sediments, more particularly in the southeastern part of the northern Province.

The continuation of mineralizing processes in areas containing radioelement-enriched buried granites, long after the emplacement of those intrusions (see refs 9, 24, 48) is not always widely appreciated. An interesting example of extensive hydrothermal circulation has been recognized in the vicinity of a Tertiary granitic stock near Marysville, Montana<sup>49</sup>, where fluids which circulated in a diffuse fracture system are thought to have set up high thermal gradients near the stock. The igneous rocks themselves are too old for magmatic heat to be responsible for the present-day hydrothermal systems. Other examples of modern hydrothermal systems associated with Palaeozoic radiogenic intrusive bodies from the Eastern Appalachians have been described by Costain and others<sup>50</sup>. Processes of mineralization associated with such hydrothermal systems are likely to be most active in provinces of high heat flow, a consideration which focuses attention on the northern England high heat flow province.

We thank G. M. Brown, F. W. Dunning and D. A. Gray for reviews. This paper is published with the permission of the director of the Institute of Geological Sciences.

# Pacifica and New Zealand: proposed eastern elements in Gondwanaland's history

P. J. J. Kamp

Earth Sciences and Antarctic Research Unit, University of Waikato, Hamilton, New Zealand

*The origin of the sediments of the Canterbury Suite to the east of the Alpine Fault in New Zealand, cannot have derived from Marie Byrd Land before or during the breaking up of Gondwanaland. It is argued that the sediments may have derived from the lost continent of Pacifica, which is supposed to have separated from Gondwanaland in the late Palaeozoic. Such a mechanism can also account for the recurrence of similar quartzo-feldspathic sediments in California and thus of the Mesozoic dolerites and basalts in southern Africa, Antarctica and Tasmania.*

THE source of voluminous continent-derived sandstones<sup>1</sup> deposited on the Pacific margin of Gondwanaland, but oceanwards of an active arc-trench environment<sup>2</sup>, is a critical problem in the late Palaeozoic-Mesozoic geology of New Zealand and one which has wider implications for Pacific geology. Eastern Gondwanaland (Australia-Antarctica) is precluded as the chief source of the quartzo-feldspathic detritus, known as the Canterbury Suite<sup>1</sup>, for several reasons: (1) the sedimentology of the suite indicates derivation of the sediment from a source in the east (Palaeo Pacific Ocean); (2) the bulk petrography is inconsistent with transportation through the then active volcanic arc bordering eastern Gondwanaland; and (3) alternative explanations, especially of post-depositional juxtapositioning of the Canterbury and Wakatipu<sup>2</sup> Suites by strike-slip faulting subparallel to Antarctica, are excluded by the Mesozoic position with respect to Gondwanaland of the Lord Howe Rise and Campbell Plateau. I propose that this sediment was derived mainly from Pacifica<sup>3</sup>, a continent contiguous with eastern Gondwanaland until its separation from the supercontinent during the late Palaeozoic, its fragmentation in the Triassic and inclusion within the circum-Pacific Cordillera in the early Cenozoic. Pacifica may also be the hitherto unknown source of other anomalous occurrences of quartzo-feldspathic detritus around the Pacific such as the Franciscan assemblage in California<sup>4</sup>. Furthermore, the origin of the extensive Jurassic basalts and dolerites of southern Africa<sup>5</sup>, Antarctica<sup>6</sup> and Tasmania<sup>7</sup> may be related to the separation of Pacifica.

The source of the Canterbury Suite has been debated for many years, and this problem is considered here in three ways. (1) The nature of the Canterbury Suite and the evidence for derivation from an eastern continent is outlined. (2) A new Mesozoic reconstruction of New Zealand relative to Gondwanaland is presented; it is important to consider New Zealand's position as close as possible to the time of Canterbury Suite deposition because the position of accumulation is a constraint on potential source areas. (3) Other problems in

Pacific geology are considered to show that the Canterbury Suite is not an isolated anomaly, and that Pacifica is a general as distinct from a merely local explanation of the source problem.

The fundamental difference between previous hypotheses of the source of the Canterbury Suite and the hypothesis advanced here is one of invoking present continents (Australia-Antarctica) as opposed to a lost continent—Pacifica. In addition to providing a source, the Pacifica model provides a mechanism, through continental fragmentation, for the periodic and rapid derivation of huge volumes of quartzo-feldspathic sediment. Further, the separation and fragmentation of Pacifica are consistent with a generally accepted plate tectonic interpretation<sup>2</sup> of the arc-trench system that formed the adjacent Wakatipu Suite.

### Late Palaeozoic-Mesozoic New Zealand

The late Palaeozoic-Mesozoic geology of New Zealand is dominated by the juxtaposition of two contrasting detrital mineral suites, one the western volcanoclastic Wakatipu Suite of andesitic composition deposited next to the foreland, and the other the quartzo-feldspathic Canterbury Suite deposited in the Pacific Ocean further to the east<sup>1</sup> (Fig. 1). These coeval suites are considered to have formed in contrasting tectonic environments and to have been rafted together in the Mesozoic which culminated in a collision—the Rangitata Orogeny—with intense deformation, metamorphism, uplift and erosion<sup>2</sup>.

The Canterbury Suite comprises two-thirds of the Rangitata Sequence<sup>8</sup> and has an estimated<sup>9</sup> thickness of 30,000 m which is not a true stratigraphical thickness but caused by tectonic stacking or a shifting dopocentre. Derivation from a terrain of granodiorite and minor schistose and metamorphic rock is indicated by the composition of the dominant minerals and rock fragments. In particular Triassic sandstones comprise quartz (40–50%), potash feldspar (10–15%), sodic plagioclase (20%) and minor amounts of muscovite, volcanic rock fragments and chert<sup>1</sup>. These sandstones typically average SiO<sub>2</sub> contents of

**Fig. 1** A map of the New Zealand sub-continent, defined by the 2,000-m isobath, showing the on-land distribution of Palaeozoic foreland rocks<sup>52</sup> and the late Palaeozoic-Mesozoic basement rocks of the Rangitata Sequence<sup>43</sup>. The Canterbury Suite-Wakatipu Suite boundary in southern South Island lies within the Haast Schist belt<sup>1</sup>, and has not been mapped; the boundary shown here is estimated. In North Island the boundary is placed between the Torlesse and Waipapa terrains<sup>16</sup>. Distribution of the ophiolite belt is taken from ref. 53.

67.5% (ref. 10). Tuffs are exceptionally rare. Consistent lithological homogeneity for over 500 km from eastern North Island to Otago (Fig. 1) and in time from Permian to Jurassic indicates the persistence of a continental source capable of supplying a quartzo-feldspathic assemblage for some 100 Myr. Although fossils are generally sparse, those that occur range from late Carboniferous to early Cretaceous<sup>11,12</sup> and biostratigraphic zonation indicates a westward and northward younging of the sediments<sup>2,13</sup>.

Based mainly on the distribution of fossil ages<sup>1</sup> deposition of the Canterbury Suite was remarkably episodic with a small pulse in the late Permian (early Tatarian), a very large pulse in the late early to late Triassic (Ladinian–Norian) and a further large pulse in the late Jurassic (early Kimmeridgian to early Tithonian). The extensive occurrence of a thick Jurassic *mélange* belt which includes reworked Triassic Canterbury Suite sediments<sup>14</sup>, suggests that much of the Jurassic sedimentation pulse was more related to erosion of the earlier Triassic sediments, as a consequence of uplift associated with the first phase of the Rangitata Orogeny<sup>8</sup>, than to tectonic events in the continental source area.

The distribution of depositional facies, detrital conglomerate, plant fossils and the records of directional sedimentary structures all indicate that sediment transport was in all directions and chiefly to the west and north, with non-marine, marginal marine and shallow marine environments in the east and an ocean basin environment in the west<sup>1,15</sup>. The Canterbury Suite thus seems to have been a huge clastic wedge<sup>8</sup> which prograded westward towards a trench, northward to eastern North Island<sup>16</sup>, and southward to a peripheral euxenic deep-marine environment at Chatham Island<sup>17</sup>.

The stratigraphical and sedimentological evidence points towards an eastern source for the Canterbury Suite. Based on the persistence of a similar composition for ~100 Myr, the quantity of sediment and the rate of sediment supply, a primary cratonic region rather than a late Precambrian or Palaeozoic orogenic belt is indicated. Furthermore, the sandstone composition together with the rate of sediment supply in the Triassic, implies rapid uplift in the source area with vigorous physical erosion and with rapid transport to the sea. In short, there seems to have been an orogeny in the source area which climaxed in the Triassic. Hence, there are mechanistic requirements for the source area in addition to constraints on its composition.

In contrast, the Wakatipu Suite (Fig. 1), derived from a calc-alkaline terrain, shows a pronounced lithostratigraphic change from early and middle Permian volcanics, volcanogenic sediments and intrusives, to late Permian, Triassic and Jurassic highly volcanogenic, mostly marine and locally richly fossiliferous sediments, with common tuffs, but no flows. The complex stratigraphy of the Wakatipu Suite is interpreted<sup>2,15</sup> as representing the development in the early Permian of a volcanic arc–trench environment followed later by formation of a subduction zone accretionary wedge and mid-slope basin deposits, and finally a regressive frontal arc wedge of upper slope and slope basin, shelf and non-marine sediments.

### Jurassic reconstruction of modern Gondwanaland

A central problem in reconstructing the Jurassic configuration is the age of the recurved arc through New Zealand, delineated by the Ophiolite belt (Fig. 1). One idea<sup>18,19</sup> is that the curve is Cenozoic in age and formed by 500 km of dextral strain associated with movement on the Alpine Fault. Such models show New Zealand as a linear feature in the late Mesozoic<sup>18,20</sup>, or incorporate 1,000 km of Cenozoic dextral displacement, 500 km of which is attributed to distributed dextral strain<sup>21–23</sup>. Although some Cenozoic crustal strain cannot be excluded<sup>24–26</sup>, 500 km of Cenozoic strain requires excessive distortion of the present outline of New Zealand and this has not been substantiated. An alternative idea is that the bending originated mainly in the Rangitata Orogeny (early Jurassic to mid-

Cretaceous)<sup>8,27,28</sup>. Palaeomagnetic data from South Island<sup>29</sup> and Chatham Island<sup>30</sup> (Fig. 1) seem to preclude significant post-late Cretaceous bending between these localities and may support bending during the Rangitata Orogeny. Furthermore, deformation studies<sup>31</sup> have established the existence of a late Jurassic bend after removing 200 km of Cenozoic dextral strain, an amount which did not excessively distort elements of the land. In the reconstruction to be discussed 200 km of Cenozoic distributed dextral strain is considered to have occurred.

There are two assumptions used in the reconstruction presented as Fig. 2: (1) There has been no major relative movements between Marie Byrd Land and East Antarctica since the late Palaeozoic. (2) There was no relative movement between Marie Byrd Land and the Campbell Plateau in the interval from the late Palaeozoic to the late Cretaceous.

The first assumption is considered to be valid because of the close correspondence in lithologies, ages and structural trends of the Palaeozoic to late Cretaceous geology of North Victoria Land, Marie Byrd Land, New Zealand and Tasmania<sup>32,33</sup>. Each region was affected by a pre-Silurian–late Ordovician metamorphic event and a widespread phase of late Devonian–Early Carboniferous (350–390 Myr BP) plutonism<sup>33</sup>. In Antarctica the trend of the Borchgrevink Orogen extends uninterrupted from the Ford Mountains in western Marie Byrd Land north-northwest through the Ross Sea basement to north-east Victoria Land<sup>34</sup>. Moreover, two Albion to Neocomian (90–142 Myr BP) calc-alkaline magmatic arcs extended from Queensland through New Zealand to Marie Byrd Land before the late Cretaceous break-up<sup>32</sup>. In addition, there is no palaeomagnetic evidence to support large displacements (~10<sup>3</sup> km) between Marie Byrd Land and East Antarctica after the late Cretaceous–early Cenozoic<sup>22</sup>, nor is there evidence during this time for the closing of an ocean basin<sup>34</sup>.

Concerning the second assumption, there are few independent lines of evidence to test the good morphological fit<sup>35</sup> of Campbell Plateau and Marie Byrd Land. In pre-Late Cretaceous times Campbell Basin was a continuation of a sediment-filled trough underlying the eastern Ross Sea shelf<sup>36</sup>. Such a structure would presumably preclude significant late Palaeozoic to late Cretaceous relative movement between Marie Byrd Land and Campbell Plateau.

Because greater New Zealand did not become a landmass until the Rangitata Orogeny (late Triassic to mid-Cretaceous<sup>8</sup>) it is difficult to establish the relative positions of the Canterbury and Wakatipu Suites before the Jurassic, and hence a later Jurassic reconstruction is presented here (Fig. 2). Although some strike-slip faulting may have occurred between the suites in the time between the late early-to late Triassic pulse of sedimentation (Canterbury Suite) and the later Jurassic, it was probably of a small scale (several hundred kilometres), and of dextral character, based on the nature of Cenozoic strike-slip faulting in the New Zealand region.

### Source of the Canterbury Suite

The present non-occurrence of a continent east of New Zealand has led to several proposals invoking a source in the west (North Victoria Land–Tasmania–Victoria (Australia)) or in the south-east (Marie Byrd Land). To enable deposition from the west without contamination by volcanoclastic detritus, bypassing mechanisms have been invoked<sup>13</sup>. However, this idea has been largely discredited on the basis of facies properties and sedimentary environments in the Canterbury Suite<sup>1,37</sup>. Transport between basins of Wakatipu Suite deposition has also been proposed as a working hypothesis for sedimentation and tectonics in the New Zealand geosyncline<sup>16</sup>. However, the extent and continuity of the Stokes Magnetic Anomaly System<sup>19</sup> precludes the occurrence of a break in the arc of sufficient size through which the whole of the Canterbury Suite could have been transported without any contamination by volcanoclastic detritus. A development of the western source is the idea that the sediments were derived from an erosional episode in the Carboniferous before the arc–trench environment formed<sup>31</sup>, but

**Fig. 2** A later Jurassic palaeogeographic map of eastern Gondwanaland with Antarctica in its present-day position. The New Zealand subcontinent is reconstructed against Norton and Sclater's fit<sup>54</sup> of Australia and Antarctica. Q, Queensland; NC, New Caledonia; T, Tasmania; NVL, North Victoria Land; LHR, Lord Howe Rise; NR, Norfolk Ridge; STR, South Tasman Rise; F, Fiordland; NN, Northwest Nelson; NI, North Island; SI, South Island; RS, Ross Sea; CP, Campbell Plateau; CI, Chatham Island. The continental outlines of New Zealand<sup>55</sup>, Australia<sup>56</sup> and Antarctica<sup>57</sup> are taken as the 2,000-m isobath. The line of 'E's' indicates the eastern limit of the pre-late Palaeozoic foreland and the line C-C' relates to the cross-section in Fig. 3. This reconstruction was made by initially establishing the extent, shape and position of the foreland, and then attaching to the foreland margin the 'post-orogenic' form<sup>31</sup> of the Rangitata Sequence. The southwestern extent of the pre-late Palaeozoic Lord Howe Rise<sup>58</sup> was taken from borehole data<sup>59</sup>. The margin of the foreland in Campbell Plateau, which has not been mapped, was placed 130 km south of the ophiolite belt<sup>53</sup>; an equivalent position to the corresponding distance immediately on-land in southeastern South Island (Fig. 1). This position of the margin in Campbell Plateau is consistent with the geology of Campbell Island<sup>60</sup> (Fig. 1), and is similar to an earlier estimate of the margin<sup>52</sup>. 480 km of Cenozoic<sup>61,62</sup> dextral transcurrent displacement on the Alpine Fault was reversed. The Waipounami Fault<sup>63</sup> is considered to be the boundary off eastern South Island where foreland rocks and the Rangitata sequence of Campbell Plateau have been brought into juxtaposition by Cenozoic drifting<sup>22</sup> of the New Zealand sub-continent. The late Cretaceous<sup>64,65</sup> Bounty Trough and Cenozoic<sup>66</sup> Waiau Basin-Solander Trough are closed. The fit of Lord Howe Rise against Australia is the conjectural pre-drift position of the Australian margin based on extrapolation of the Australian margin at the time anomaly 33 formed<sup>67</sup> (82 Myr BP). The reconstruction of Campbell Plateau and Antarctica is a morphological fit<sup>55</sup>. New Caledonia and Norfolk Ridge are placed against Lord Howe Rise. About 100 km of dextral transcurrent displacement is involved to bring the southern part of Norfolk Ridge into the best visually determined morphological fit with Lord Howe Rise. In this reconstruction North Island occurs in a position slightly further south and oceanward of its present position relative to Lord Howe Rise.

such a theory requires an elaborate mechanism to explain the subsequent wholesale reworking westwards back towards the trench.

An eastern source area is now more acceptable although the location has not been specified<sup>1,2,15,38</sup>. In attempts to improve the definition of the eastern source it has been proposed<sup>37</sup> that the Canterbury Suite was formed from sediment derived from Marie Byrd Land and transported northwestwards. However, the Jurassic reconstruction of New Zealand relative to Gondwanaland presented here (Fig. 2) precludes Marie Byrd Land as the source because it lies on the back-arc side of the Canterbury Suite. Moreover, the shape of the clastic wedge comprising the Canterbury Suite is opposite to that expected if Marie Byrd Land were the source; Chatham Island sediments were deposited in a euxenic deep-marine environment yet in a pre-late Cretaceous position (Fig. 2) occur nearer to Marie Byrd Land than the non-marine and shallow marine deposits more distant in South Island.

An alternative idea also involving Marie Byrd Land as the source, but invoking strike-slip faulting of the Canterbury Suite subparallel to the Palaeo Pacific margin of Antarctica has been proposed<sup>39,40</sup>, but not applied to a rigorous Mesozoic reconstruction of eastern Gondwanaland and New Zealand. In taking the later Triassic reconstruction presented here (Fig. 3), and noting particularly the extent of the volcanic arc, to avoid transportation through the arc-trench system some 2,000 km of sinistral strike-slip movement would be required to derive the Canterbury Suite from more eastern parts of Marie Byrd Land. Moreover, the bulk of this movement would need to have occurred between the late early and late Triassic pulse of sedimentation and the first phase of the Rangitata Orogeny (late Triassic-early Jurassic<sup>8</sup>). No mechanism has been proposed and substantiated to account for such rapid movement, and it is in an

opposite sense to Cenozoic strike-slip movement in New Zealand. A model invoking strike-slip faulting would be acceptable only if a lesser amount of fault movement were necessary. This could apparently only be achieved by arbitrarily twisting the Campbell Plateau and Lord Howe Rise into different positions during the Mesozoic, such that until the mid-Jurassic the Canterbury Suite was more proximal to source, yet, by the mid-Cretaceous the Campbell Plateau and Lord Howe Rise were in the pre-breakup late Cretaceous positions. There is no evidence to suggest that before the mid-Cretaceous the Campbell Plateau and Lord Howe Rise had different positions relative to Antarctica and Australia, and hence there is not a substantiated case for Marie Byrd Land as the source of the Canterbury Suite.

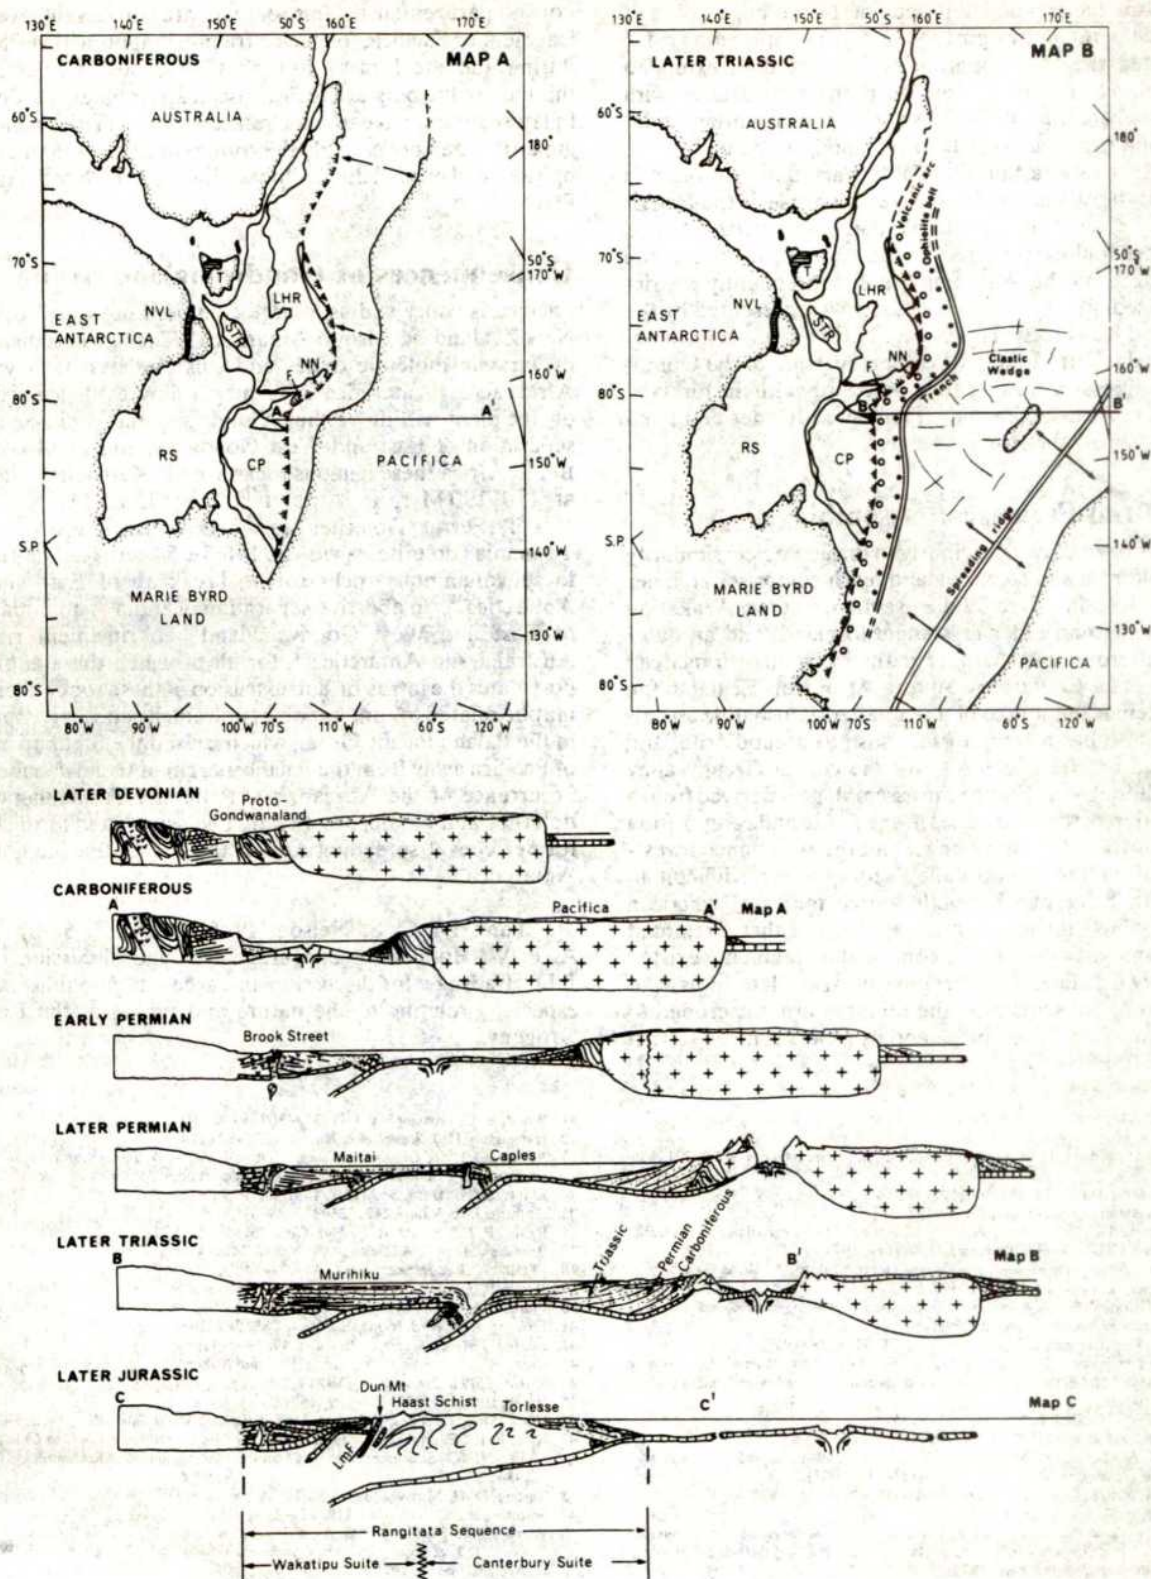

### Pacifica and development of New Zealand

Pacifica was a continent hypothesized from geological evidence<sup>3</sup> to have lain off eastern Gondwanaland until the Triassic. It then fragmented and now occurs as exotic blocks of continental crust within the circum-Pacific Cordillera. The recent demonstration<sup>41</sup> that large parts of western North America are allochthonous adds credibility to Pacifica's fragmenting and subsequently contributing to formation of the Pacific Cordillera.

In discussing Lost Pacifica, Nur and Ben Avraham<sup>3</sup> did not use stratigraphical evidence from New Zealand to support their argument. Pacifica may well be the source of the Canterbury Suite<sup>42</sup>. Not only was Pacifica in the correct position at the right time, but its fragmentation also provides the mechanism for deriving huge volumes of Permian and Triassic sandstone.

I largely agree with the plate tectonic interpretations<sup>2,4,31</sup> for the Wakatipu Suite and the subsequent collision of the two suites, but seek to extend these models eastwards by including Pacifica (Fig. 3).

**Fig. 3** Palaeogeographic maps and schematic cross-sections illustrating a model of the late Palaeozoic-Mesozoic geological development of New Zealand. These show a relationship of the plate tectonic development of the Wakatipu Suite<sup>2,31</sup> and derivation of the Canterbury Suite, to the drift and fragmentation of Pacifica. The later Jurassic cross-section relates to the section line in Fig. 2. The details of map construction and abbreviations are given in Fig. 2, and the terrain names on the cross-sections (for example, Brook Street) are defined elsewhere<sup>2</sup>.

The Rangitata sedimentary-orogenic cycle<sup>43</sup> is postulated to have begun in the late Devonian to early Carboniferous with rifting within the Tuhua Orogen (Fig. 3); fragmentation of supercontinents is believed commonly to occur along old orogenic belts<sup>44</sup>. The spreading centre probably propagated southwards. A reconstruction of New Zealand for the Carboniferous (Fig. 3, map A) shows that the foreland was curved and

the corresponding embayment in Pacifica might have promoted delta formation of the Canterbury Suite. By the Early Permian the Wakatipu arc-trench environment had formed and by the mid-Permian an incipient fracture had developed within Pacifica. The fragmenting of Pacifica (Fig. 3) ensured extensive uplift of the continent during the late Permian and Triassic and derivation, by physical erosion, of detritus which preserved a

quartzo-feldspathic composition because of the huge volumes involved and the rapid transport to the sea. The spreading ridge which initiated the fragmentation of Pacifica then extended south to Antarctica (Fig. 3, map B), perhaps associated with anticlockwise rotation of Gondwanaland concomitant with transformation from Panagea B to A<sup>45</sup>, and by the end of the Triassic was actively rafting the Canterbury Suite on oceanic crust towards the Wakatipu Suite. The first phase of the Rangitata Orogeny ensued in the late Triassic-early Jurassic<sup>8</sup>, and although most folding occurred in the Canterbury Suite, the wedge impinged on the Wakatipu Suite, consequently restricting Jurassic sedimentation to the areas now represented by the Southland and Kawhia Synclines (Fig. 1). The point collision of the clastic wedge (Fig. 3, map B) caused eversion of the Ophiolite and its progressive convergence westwards with the foreland (Fig. 2). In the Jurassic, Pacifica fragmented further and parts were drifting across the Pacific Ocean.

## Source of the Franciscan assemblage

Attention has been drawn previously to the geological similarity between California and New Zealand: each comprises an inner volcanogenic terrain (Great Valley sequence versus Wakatipu Suite) adjacent to an older crystalline foreland, and an outer rarely fossiliferous quartzo-feldspathic terrain (Franciscan assemblage versus Canterbury Suite)<sup>4</sup>. As in New Zealand, the critical problem is the source of the quartzo-feldspathic assemblage which also has a composition close to granodiorite, and was deposited on the Pacific side of the coeval Great Valley sequence. Although the Franciscan assemblage is derived from a continental source, the differences in grain-size and composition between the two sedimentary belts, and the pronounced westward thinning of the Great Valley sequence, are difficult to reconcile with a Sierran-Klamath source for the Franciscan assemblage<sup>4</sup>. This difficulty led to the proposal that a remnant volcanoplutonic arc, possibly a continental fragment, existed between the two sedimentary terrains during the late Jurassic to early Tertiary<sup>46</sup>. Subsequently, the remnant arc was eroded to derive the Franciscan assemblage and its roots subducted so that

now no part remains<sup>4</sup>. This remnant arc could well have been a fragment of Pacifica, for such a fragment approached California during the late Jurassic to early Cretaceous<sup>3</sup>. Consistent with this model, the bulk of the Franciscan assemblage was deposited in latest Jurassic to earliest Cretaceous time (Tithonian-Valanginian)<sup>4</sup>, when presumably the continental fragment was rapidly uplifted and eroded due to interaction with the North American Plate.

## Consequences of Gondwanaland rifting

Pacifica is conceived as a large continent not only adjacent to New Zealand but also to Antarctica<sup>3</sup>. The age and distribution of Jurassic tholeiitic dykes and sills and basaltic lavas from Africa across Antarctica to Tasmania show evidence of a period of incipient rifting within Gondwanaland well before the separation of East and West Gondwanaland at 140–160 Myr BP. In Africa these igneous rocks are the Karroo Basalts dated<sup>3</sup> at 150–190 Myr, in Antarctica the 175±5 Myr old Dufek Massif, Ferrar Dolerites and Kirkpatrick Basalts<sup>47</sup>, and in Tasmania, dolerites aged<sup>7</sup> at 170.5±5 Myr. Rather than link these voluminous rocks to the break-up of East and West Antarctica<sup>48</sup>, an abortive separation of India<sup>49</sup>, an initial rifting of East and West Gondwanaland<sup>50</sup>, or incipient rifting of Australia and Antarctica<sup>51</sup>, for all of which the age of rifting post-dates the intrusion and extrusion of these rocks, their origin may be related to contemporary volcanicity and active spreading in the Palaeo Pacific Ocean which caused the breakup and drift of Pacifica away from the Pacific margin of Gondwanaland. The occurrence of the African, Antarctic and Tasmanian Jurassic dolerites and basalts has already been suggested as related to a former coeval spreading axis in the Palaeo Pacific Ocean off Antarctica<sup>44</sup>.

I thank Dr C. S. Nelson, Professor M. J. Selby and Dr A. P. W. Hodder for encouragement and discussion, and Dr J. D. Bradshaw for discussion and access to unpublished work, especially relating to the nature and timing of the Rangitata Orogeny.

*A portion of Moloney murine sarcoma virus DNA which is repeated at both ends of the provirus has been sequenced. The nucleotide sequence, together with hybridization data obtained with in vitro pulse-labelled nascent viral RNA, indicate that initiation and termination of RNA synthesis occur within that region of the proviral DNA. A model for transcriptional readthrough of termination signals during RNA synthesis in this system is suggested.*

A CRUCIAL STEP in the life cycle of retroviruses is their integration as double-stranded DNA molecules into the DNA of the cell they infect (for a review see ref. 1). The mechanism(s) which regulates transcription of integrated DNA into viral RNA and viral mRNAs has been actively investigated. However, although it is known that cellular RNA polymerase II mediates transcription of the viral genome<sup>2-5</sup>, little is known about the actual sites for initiation and termination of transcription; for example, whether these sites reside on host cell DNA or viral DNA. The size of nuclear virus-specific primary transcripts has not been established; data supporting the presence of both genome-length and longer than genome-length nuclear precursors<sup>6-9</sup> have recently been reported. The discovery that integrated and unintegrated viral DNAs contain a direct repeat at both ends of the DNA and thus are longer than the viral RNA template<sup>10-15</sup> has raised some interesting questions about the potential of the proviral DNA to function as a transcriptional unit. In the case of Moloney murine sarcoma virus (MSV), the

viral DNA carries a 600, base-pair long terminal direct repeat (LTR, which contains the sequences termed XYZABCDE in Fig. 1a)<sup>11</sup>. The mature viral RNA starts and terminates within the LTR with the specific sequence termed 'ABC' (Fig. 1a). This sequence is 59 nucleotides long and is present at both ends of the viral RNA. Its role in reverse transcription has recently been elucidated<sup>16,17</sup>. The genome structure shown in Fig. 1a implies that if MSV functions as a transcriptional unit, the LTR must contain sequences that code for the initiation and termination of RNA synthesis. Alternatively, if transcription starts and terminates outside the proviral DNA, the LTR must carry the information necessary for RNA processing.

We report here DNA sequence data obtained from the LTR DNA cloned into a bacterial plasmid, pBR322. The nucleotide sequence upstream from the region of DNA which codes for the 5' end of the viral RNA (capping site) contains the sequence CAATAAAA, a variation of the typical 'Hogness box', which has been associated with promotion or initiation of transcription

**Fig. 1 a**, Relationship between genomic MSV RNA and integrated DNA. The structure of MSV DNA has been drawn according to results obtained with unintegrated and integrated MSV double-stranded DNA<sup>11,43,46</sup>. The 600-base pair direct repeats (LTRs) are represented by hatched areas. The sequence ABC corresponds to the 59-nucleotide repeat present at either end of viral RNA (ref. 32 and Fig. 3); transcription is from left to right. kb, Kilobases. **b**, Schematic representation of recombinant plasmid p-600-3 from which SacA and SacB DNA fragments were derived. The 600-base pair DNA (LTR) was prepared *in vitro* and purified on agarose gels as described previously<sup>17</sup>. Briefly, S<sub>1</sub> nuclease-treated LTR DNA was tailed with oligo(dC) and plasmid pBR322, cleaved at the PstI site and tailed with oligo(dG). After annealing, the recombinant molecules were selected and amplified in *E. coli*  $\chi$ 1776. Screening was performed with 'strong-stop' MSV cDNA<sup>17,47</sup>. The map of pBR322 is drawn in an anticlockwise orientation. The insert represents the majority of the LTR DNA present on full-length genomic DNA. Its length is 572 nucleotides, of which 518 are viral and the rest G-C tails. Fifty nucleotides are missing from the right end of the sequence and ~15 nucleotides have been deleted at the left end. The numbers +1, +59 and -26 indicate the coordinates of RNA transcription (see Fig. 2) which proceeds from left to right. The SacA and SacB fragments were obtained by digestions with the restriction endonucleases SacI and BamHI. DNA fragments were separated on 5% polyacrylamide gels and electroeluted into dialysis bags. After ethanol precipitation, 1  $\mu$ g of purified DNA was loaded on to Millipore filters. The filters were processed for hybridization and stored under vacuum.

in many of the eukaryotic genes which have been sequenced. The Hogness box is followed by a AATAAA poly(A)-addition signal 70 nucleotides downstream. Hybridization data obtained with *in vitro* pulse-labelled nuclear RNAs indicate that initiation of transcription occurs close to or at sequences corresponding to the viral RNA capping site. The relative position of initiation and polyadenylation sites suggests that a readthrough mechanism may be used in synthesis of mature viral RNA. The potential secondary structure of the RNA transcribed from this portion of the viral genome suggests that in MSV, chain termination may occur by a mechanism similar to attenuation in bacteria<sup>18,19</sup>. A model for such a regulatory mechanism is suggested here.

## DNA sequence data

The long terminal repeat (LTR) present on the unintegrated and integrated viral DNA participates in several crucial steps of the virus life cycle, including DNA synthesis, integration and transcription. To establish whether any specific structural features contained within the LTR might clarify its role in transcription, we have determined the nucleotide sequence of a recombinant plasmid (p-600-3) carrying an insert which represents 518 base pairs of the LTR DNA (Fig. 1b).

Figure 2 shows the nucleotide sequence of the last 177 base pairs (3' end) of the LTR DNA. A Hogness box, which has been found in the majority of eukaryotic genes transcribed by RNA polymerase II (refs 20-23 and ref. 24 for a review), is found 26 nucleotides upstream from the capping site. Although this sequence has been previously considered the structural equivalent of a bacterial 'Pribnow box' (ref. 20), and therefore a promoter, recent evidence suggests that it confers homogeneity

**Fig. 2** Sequence of the right end of the LTR DNA. For sequencing, the 572-base pair insert was released from the plasmid by digestion with *Pst*I and purified on a 5% polyacrylamide gel (acrylamide/bis = 30:1, 20 cm × 20 cm × 1.0 cm). This fragment was digested with *Pvu*II, *Ava*I, *Hha*I, *Sma*I or *Sac*I and end labelled with T4 polynucleotide kinase and [ $\gamma$ -<sup>32</sup>P]ATP (3,000 Ci mmol<sup>-1</sup>, Amersham) or terminal transferase and 3'-[ $\alpha$ -<sup>32</sup>P]dATP (1,000 Ci mmol<sup>-1</sup>, NEN). For strand separation the labelled DNA fragments were dissolved in 30  $\mu$ l of 0.3 M NaOH, 10% glycerol (v/v), 1 mM EDTA and 0.05% bromophenol blue and xylene cyanol, heated at 90°C for 2 min, chilled on ice and immediately fractionated on a 5% polyacrylamide (acrylamide/bis, 60:1) strand-separation gel at 300 V at room temperature in 50 mM Tris-borate, pH 8.3, 1 mM EDTA buffer. These singly end-labelled fragments were sequenced by the chemical cleavage method of Maxam and Gilbert<sup>48</sup>. The nucleotide sequence of both DNA strands was determined except for the last 50 nucleotides. This portion of the sequence has been obtained from strong-stop MSV cDNA synthesized *in vitro*<sup>17</sup>. +1 Indicates the first nucleotide on the viral RNA map, +59 the last one. The Hogness box and the polyadenylation signals are underlined.

to the starting nucleotide or capping site of the transcripts<sup>23</sup>. In its absence, heterogeneous 5' ends are found, but initiation of RNA synthesis is maintained<sup>22,23</sup>. The presence of such a structural element on MSV DNA argues in favour of the possibility that synthesis of mature viral RNA may actually start at this site and that the nucleotide sequence surrounding the capping site and including the Hogness box may serve as a promoter *in vivo*.

A second specific structure, reported for many of the genes transcribed by RNA polymerase II, is the polyadenylation signal AATAAA. This sequence, found at position +45, is followed by another sequence, TTGC or TTTGC<sup>24,25</sup>, at position +63 to +67, immediately downstream from the presumed terminal tetranucleotide TTGC. Comparative data for several other mRNAs<sup>24</sup> and viral RNAs<sup>25,26</sup> indicate that this region is associated with termination of RNA transcription. If transcriptional processes *in vivo* actually use the structural regions described above as regulatory signals, it follows that the LTRs of integrated proviral DNA have a promoter region immediately adjacent to terminator signals.

## Does transcription of MSV RNA start at a cellular or viral promoter?

The presence of sequences in the LTR DNA which correspond to the putative promoter sites of several eukaryotic genes<sup>24</sup> transcribed by RNA polymerase II raises the specific question of whether or not virion RNA is the primary product of nuclear transcription in infected cells. We have therefore isolated nascent, pulse-labelled nuclear RNA synthesized *in vitro* and analysed it by hybridization to different portions of the p-600-3 plasmid DNA (Fig. 2). If transcription started at a cellular site upstream from the viral 'promoter site' (marked -26 in Fig. 1b), LTR sequences (XYZ) upstream from the *Sac*I site would be transcribed and covalently linked to downstream sequences (ABCDEF). If instead transcription started at the putative viral promoter site (Fig. 1b), the 5' ends of virus-specific nuclear RNAs would correspond only to sequences downstream from the *Sac*I site (ABCDEF). By hybridizing *in vitro* pulse-labelled nuclear RNA to LTR sequences downstream from the promoter (*Sac*A fragment, Fig. 1b) or LTR sequences upstream from the promoter (*Sac*B fragment, Fig. 1b), the relative amounts transcribed from these two regions of the LTR DNA have been quantified. This analysis must, however, take into account the fact that mature virion RNA ends with the sequence XYZABC, which can hybridize to both the *Sac*A and *Sac*B fragments. (Table 1 summarizes the distribution of virus-specific nucleotides on the *Sac*A and *Sac*B fragments.) Therefore, before hybridization, we removed polyadenylated mature viral RNA from the nuclear RNA sample by chromatography on oligo(dT)-cellulose (see Table 2 legend). Mature virion RNA was fragmented by alkaline treatment<sup>27</sup> and fractionated by oligo(dT) chromatography. Viral poly(A)<sup>+</sup> and poly(A)<sup>-</sup> RNA fragments were used as controls in the hybridization to DNA-nitrocellulose filters. DNA-nitrocellulose filters carrying specific DNA fragments were prepared as described in Fig. 2 legend.

**Table 1** Distribution of virus-specific sequences on *Sac*A and *Sac*B fragments

| Fragment     | Total virus-specific nucleotides | %   | Nucleotides complementary to 5' viral RNA |    | Nucleotides complementary to 3' viral RNA |    |
|--------------|----------------------------------|-----|---|----|---|----|
|              |                                  |     |   | %  |   | %  |
| p-600-3      | 518                              | 100 | 91  | 17 | 486                                       | 94 |
| <i>Sac</i> A | 128                              | 25  | 91  | 17 | 96  | 18 |
| <i>Sac</i> B | 390                              | 75  | 0   | 0  | 390                                       | 75 |

The number of nucleotides on each fragment was derived from the sequencing data presented in Fig. 2 and unpublished results. The number of hybridizable virus-specific nucleotides from either end of the viral RNA was calculated by taking into account the presence of the 59-nucleotide ABC repeat at the end of the viral RNA. The *Sac*A fragment contains 'promoter-downstream' sequences (ABCDEF) and the *Sac*B fragment carries 'promoter-upstream' sequences (XYZ) (Fig. 1b).

**Table 2** Hybridization of pulse-labelled nuclear RNA from MSV-infected cells to p-600 DNA fragments

| Viral poly(A) <sup>-</sup>   | 1.12 × 10 <sup>5</sup> | 2,507 (30)                          | 5,988 (70)                          |

Approximately  $2 \times 10^7$  cells were directly lysed on the plate by addition of lysis buffer (25 mM Tris-HCl, pH 7.4, 25 mM NaCl, 5 mM MgCl<sub>2</sub>, 140 mM sucrose, 0.5% Triton X-100). After 10 min in the cold, cells were scraped off the plates with a Teflon-coated razor blade. Complete lysis was achieved by subjecting the cells to 10 strokes with a B pestle in a Dounce homogenizer. Nuclei were pelleted through a sucrose cushion (0.25 M sucrose, 5 mM MgCl<sub>2</sub>, 25 mM Tris pH 7.4) at 4 °C with a table-top centrifuge. The nuclear pellet was resuspended in 1.5 ml of buffer (0.25 M sucrose, 5 mM MgCl<sub>2</sub>, 25 mM Tris pH 7.4) and pelleted again. Final recovery was  $1.1 \times 10^7$  nuclei. The crude nuclei were gently suspended in 150 µl of a solution containing 125 mM Tris pH 7.9, 2 mM MgCl<sub>2</sub>, 5 mM NaF, 1 mg ml<sup>-1</sup> bovine serum albumin, 1 mM ATP, GTP and CTP, 5.8 µM [ $\alpha$ -<sup>32</sup>P]UTP, 50 mM (NH<sub>4</sub>)<sub>2</sub>SO<sub>4</sub> and 1 mM dithiothreitol. The reaction was incubated at 37 °C for 5 min and terminated by the addition of 500 µl of 50 mM Na-acetate pH 5, 6 mM EDTA and 1% SDS. Total incorporation measured by trichloroacetic acid precipitation was  $\sim 3 \times 10^7$  c.p.m. Nuclear RNA was extracted several times with phenol saturated with 0.1 M Na-acetate pH 5.0. After ethanol precipitation, the poly(A)-containing nuclear RNA was fractionated by chromatography on oligo(dT)-cellulose. An aliquot of each RNA fraction was then hybridized to specific p-600 DNA fragments bound to nitrocellulose filters in 1 ml of HEPES hybridization buffer (100 mM HEPES, pH 7, 1 mM EDTA, 0.2% SDS, 0.5 M NaCl and 50% formamide, 48 h at 40 °C). The filters were washed extensively in 2 × SSC at 65 °C and treated with RNase (20 µg ml<sup>-1</sup>, 2 × SSC at room temperature for 1 h). Hybridization experiments were performed in triplicate. In these experiments nonspecific background values (10 c.p.m. per 10<sup>6</sup> c.p.m.) were subtracted from the results presented above.

The nuclear RNA samples labelled with [ $\alpha$ -<sup>32</sup>P]UTP and mature virion RNAs uniformly labelled with <sup>32</sup>P-orthophosphoric acid were hybridized to DNA filters stacked in a scintillation vial (Table 2). If the oligo(dT)-cellulose chromatography step removed all the RNA chains containing the XYZABC portion of the LTR located at the 3' end RNA, the viral poly(A)<sup>-</sup> RNA fragments should hybridize exclusively to the SacA DNA-containing filter. Although the majority of poly(A)<sup>-</sup> RNA counts hybridized to SacA DNA (Table 2), a substantial background (30%) of viral poly(A)<sup>-</sup> RNA hybridized to SacB DNA, implying that oligo(dT)-cellulose chromatography could not completely remove all 3'-terminal fragments of viral RNA molecules. This was not surprising as 10–30% of full-length virion RNA lacks a poly(A) tail (ref. 28 and D.D., unpublished observation). Similarly, we observed that 60% of virus-specific, poly(A)<sup>-</sup>, pulse-labelled nuclear RNA counts hybridized to SacA DNA whereas 40% hybridized to SacB DNA (Table 2). This result implied that pulse-labelled, virus-specific nuclear RNA was very similar to mature virion RNA and that newly synthesized nuclear RNA started primarily at a site on the SacA fragment.

To eliminate the ambiguity due to the background hybridization of 3' sequences in the experiment described above, another experiment was devised. The pulse labelling was performed in the presence of ribonucleoside triphosphate analogue which contained a sulphur atom substituted for oxygen in the  $\gamma$  phosphate position ( $\gamma$ -S NTPs) (see Table 3 legend). Newly initiated chains have the structure  $\gamma$ -S pppN <sup>32</sup>pUp. The incorporation of a  $\gamma$ -S nucleotide at the 5' end of a chain prevents capping of that chain (Furichi and R. N. Wydro, unpublished results), thus allowing its purification by mercury-agarose affinity chromatography<sup>29</sup>. Therefore, RNAs retained by the column terminate with 5'  $\gamma$ -S triphosphate, indicating that these RNAs result from initiation during the pulse label and not from elongation. Because most RNA chains in eukaryotic nuclei start with G or A, only those two substrates were actually used.

After fractionation of the RNA on mercury-agarose columns (see Table 3), a fraction containing the bulk of the nuclear RNA (unbound RNA) and a fraction containing  $\gamma$ -S pppA- and  $\gamma$ -S pppG-initiated chains were obtained (Table 3). The percentage of RNA chains initiated with a substituted nucleotide was

approximately 3% of the total [ $\alpha$ -<sup>32</sup>P]UTP-labelled chains, in agreement with previously obtained results<sup>30,31</sup>. The 'bound' and 'unbound' fractions were hybridized to nitrocellulose filters carrying the SacA and SacB fragments as described above. The hybridization pattern of the unbound fractions of the RNA made in the presence of  $\gamma$ -S ATP and  $\gamma$ -S GTP were quantitatively similar, being proportional to the number of virus-specific nucleotides present on the SacA and SacB fragments (Table 1). This result showed that the substituted nucleotides did not interfere significantly with the elongation of virus-specific RNA chains and that transcription of the whole viral genome occurred.  $\gamma$ -S pppG-initiated chains hybridized preferentially to the SacA fragment. When normalized to the number of virus-specific nucleotides of the SacA and SacB fragments (Table 1), the ratio of the counts hybridized to SacA compared with SacB DNA was greater than 20:1. From these data we concluded that most of the virus-specific RNA chains were initiated within the SacA fragment. The counts which hybridized to the SacB fragment could be due either to the presence of contaminating total RNA in the bound fraction or to a small number of chains initiated at a cellular promoter. The small number of hybridized counts obtained with  $\gamma$ -S pppA-initiated chains supports the conclusion that sulphur groups were not transferred to internal residues of elongating chains.

### A model for chain termination

The evidence presented here strongly suggests that initiation of viral RNA synthesis occurs at a site on proviral DNA contained within the last 177 nucleotides of the 600-base pair repeat. Because the 5' and 3' ends of the primary transcripts of many RNA polymerase II-dependent transcriptional units are conserved during processing of precursor nuclear RNA into mature mRNA (for a summary see refs 24, 25), it is reasonable to assume that virus-specific nuclear RNA chains have the same 3' end as mature virion RNA. As shown in Fig. 3, we have tentatively placed the nucleotide which precedes the poly(A) at position +59 on the basis of oligonucleotide sequence data (ref. 32 and unpublished observations). The DNA sequence between the capping site (+1) and the region immediately following the end of the viral RNA (+59) thus contains signals for poly(A) addition and possibly chain termination. These signals must be ignored by RNA polymerase II during transcription of the LTR at the left end of the proviral DNA (see Fig. 1a); however, the enzyme would have to recognize such signals at the end of transcription, 5,400 nucleotides downstream, as it transcribes the LTR at the right end of the genome.

**Table 3** Hybridization of RNA from MSV-infected cell nuclei pulse-labelled in the presence of  $\gamma$ -S GTP and  $\gamma$ -S ATP to p-600-3 DNA fragments

| RNA sample      | Input<br>c.p.m.    | c.p.m. hybridized<br>to SacB | c.p.m. hybridized<br>to SacA |
|-----------------|--------------------|------------------------------|------------------------------|
| $\gamma$ -S ATP |                    |                              |                              |
| Unbound         | $7.92 \times 10^6$ | 2,225                        | 430                          |
| Bound           | $2.7 \times 10^5$  | 62                           | 22                           |
| $\gamma$ -S GTP |                    |                              |                              |
| Unbound         | $3.82 \times 10^7$ | 8,732                        | 2,652                        |
| Bound           | $9.67 \times 10^5$ | 108                          | 656                          |

RNA was synthesized in the *in vitro* nuclear transcriptional system described in Table 2 legend with the exception that either  $\gamma$ -S ATP or  $\gamma$ -S GTP was added in place of the respective unsubstituted nucleotide triphosphate. The RNA was extracted with phenol as described and ethanol precipitated three times. The RNA was then dissolved in the buffer (10 mM Tris-HCl, pH 7.9, 100 mM NaCl, 10 mM Na<sub>2</sub>EDTA, 0.1% SDS) and applied to a low cross-linked mercury-agarose column as described elsewhere<sup>31</sup>. The bound material was eluted with TNE buffer containing 10 mM dithiothreitol<sup>30</sup>. Eluted fractions (0.5 ml) were monitored for radioactivity by removing aliquots (3 µl for  $\gamma$ -S GTP RNA and 12 µl for  $\gamma$ -S ATP RNA) and measuring Cerenkov radiation in 1.5-ml Eppendorf tubes. Peak fractions were pooled, made 50 µg ml<sup>-1</sup> with tRNA and precipitated overnight with two volumes of ethanol at 20 °C. The RNA synthesized with  $\gamma$ -SGTP was the result of four identical *in vitro* reactions pooled before the extraction of RNA. Hybridizations were performed to filters stacked in scintillation vials as described in Table 2 legend. Experiments were performed with triplicate samples for  $\gamma$ -S GTP. The largest variation between homologous filters in each hybridization was less than 20%. Backgrounds were reproducibly 10 c.p.m. per 10<sup>6</sup> c.p.m. input and have been subtracted from the values presented above.

containing cellular sequences. Note also that our model is not incompatible with the possibility that mature viral RNA is processed from a larger precursor. In this case the large stem and loop structure at the 3' terminus would serve as a recognition site for processing. This model can be tested experimentally. Transfection of cells with plasmids containing the LTR DNA, singly and in tandem repeats, as well as subclones containing specific deletions, should offer a useful approach for studying these phenomena.

*Two independent, three-dimensional structures of yeast tRNA<sup>Asp</sup>, mainly differing by the conformation of the D loop, have been obtained from a multiple isomorphous replacement (MIR) X-ray analysis at 3.5-Å resolution. The folding of the ribose-phosphate backbone is similar to that found for tRNA<sup>Phe</sup>; major differences concern the relative positioning of the acceptor and anticodon stems, and the conformation of the loops in the two molecules. Crystal packing involves self-complementary GUC anticodon interactions.*

TRANSFER RIBONUCLEIC ACIDS are versatile macromolecules which interact with many components of the protein-synthesizing machinery. Some of the functions of these molecules, like the interaction with the ribosomes, are common to all tRNAs<sup>1,2</sup>; others, like the specific attachment to the aminoacyl-tRNA synthetases, are specific to each particular tRNA<sup>1</sup>. It is therefore expected that all these molecules possess structural similarities at the three-dimensional level, but also differences responsible for their specific functions. To understand the molecular basis of the multifunctional character of tRNA, knowledge of the structure of different tRNAs is necessary.

The first molecular structure of a tRNA obtained from electron-density maps at atomic resolution<sup>3-6</sup>, that of yeast tRNA<sup>Phe</sup>, made possible the elucidation of the folding of the polynucleotide backbone which accommodates the clover-leaf domains in a stable L-shaped structure, the structural justification for most of the invariant residues, and the evidence of tertiary interactions necessary to the stability of the structure.

These features, which might be found in all tRNAs, probably account for the general tRNA functions. The fact that similar information was obtained from two independent structures of tRNA<sup>Phe</sup>, in two different crystal forms, ruled out the possibility of distortions induced by packing forces and gave more confidence for the generality of the L-shaped structure. However, the structural data obtained on yeast tRNA<sup>Phe</sup> did not allow definitive conclusions about the features responsible for the specific functions of the tRNAs. Furthermore, the nature of conformational changes in tRNA, observed by various methods, is still uncertain<sup>7,8</sup>. These facts prompted study of the crystallization of tRNAs presenting structural and functional differences compared with tRNA<sup>Phe</sup>. Emphasis was given to obtaining good crystals of the initiator tRNAs and of tRNAs with short or long extra-loops, or of tRNAs possessing three base pairs in the D stem. In 1977, we succeeded in growing crystals of yeast tRNA<sup>Asp</sup>, which is a tRNA with a short extra-loop, diffracting better than 3.5 Å of resolution<sup>9</sup>.

**Fig. 1** The nucleotide sequence of yeast tRNA<sup>Asp</sup> (ref. 13). For convenience the numbering system of the nucleotides is that of yeast tRNA<sup>Phe</sup>; in the 75-nucleotide long tRNA<sup>Asp</sup>, position 47 in the variable loop has been omitted. Non-classical Watson-Crick base pairs are indicated by broken lines. The invariant and semi-invariant positions (except for initiator tRNAs) and the constant nucleotides in most tRNAs are indicated. Sequence data are taken from the review of Dirheimer *et al.*<sup>26</sup>. The  $\alpha$  and  $\beta$  regions correspond to the parts of the D loop located respectively at the 5' and 3' side of the constant GG sequence.

It was not until 1979 that new structural information on different tRNAs appeared. In yeast tRNA<sup>Met</sup>, which was crystallized in high-salt conditions, only a difference in the position of the anticodon stem with respect to tRNA<sup>Phe</sup> was apparent, but the resolution of the map does not allow a firm conclusion<sup>10</sup>. For the structure of *Escherichia coli* tRNA<sup>Met</sup>, solved using the molecular replacement method, changes from the tRNA<sup>Phe</sup> model were observed which may be of functional importance<sup>11</sup>. Yeast tRNA<sup>Gly</sup> is an exception with an unfolded structure<sup>12</sup>, but this tRNA was crystallized at high temperature in the presence of high amounts of organic solvent.

We report here the first structural results on another elongator tRNA, yeast tRNA<sup>Asp</sup>, based on two independent maps obtained by the MIR method from two interconvertible crystal forms diffracting at high resolution.

### Primary structure

The nucleotide sequence of yeast tRNA<sup>Asp</sup> (ref. 13, Fig. 1) presents some distinctive features compared with yeast tRNA<sup>Phe</sup> and other tRNAs studied by crystallographic methods. An exceedingly high number (nine out of 10) of GC base pairs in the TΨC and anticodon stems confers an important stability to these regions, as confirmed by solution studies<sup>14,15</sup>. Conversely, the D stem does not contain any GC base pair and is therefore particularly unstable. Due to this, the number of base pairs in the D stem of tRNA<sup>Asp</sup> is not well defined and it has long been considered as belonging to class II according to Levitt's tRNA classification<sup>16</sup>. Yeast tRNA<sup>Asp</sup> is also one of the tRNAs containing the fewest number of modified nucleotides: besides the classical D, Ψ and T residues, it only possesses one m<sup>1</sup>G and

one m<sup>5</sup>C. Concerning the general organization of the tRNA<sup>Asp</sup> clover-leaf, the  $\alpha$  and  $\beta$  regions in the D loop (three bases each) differ from those in tRNA<sup>Phe</sup> (four and two bases for the  $\alpha$  and  $\beta$  regions respectively) and the length of the variable loop (four bases) is shorter than in tRNA<sup>Phe</sup> (five bases). Another difference between the two tRNAs is the replacement at position 73 of A in tRNA<sup>Phe</sup> by G in tRNA<sup>Asp</sup>. This position has been proposed as a discriminator site for tRNA aminoacylation<sup>17</sup>. Finally, tRNA<sup>Asp</sup> possesses a self-complementary GUC anticodon<sup>18</sup> which renders it a tempting model system for studying tRNA-mRNA interactions.

### Crystal analysis

We used 150 mg of pure tRNA<sup>Asp</sup>, purified from brewer's yeast tRNAs by countercurrent distribution followed by benzoylated DEAE-cellulose chromatography. For crystallization, tRNA<sup>Asp</sup> was used as a sodium salt, prepared by dialysis against 40 mM sodium cacodylate buffer containing 2 mM MgCl<sub>2</sub>. Crystals were obtained in 62% ammonium sulphate using vapour diffusion techniques<sup>9</sup>. The temperature was a decisive parameter in crystal growth. Crystals suitable for diffractometer measurements were obtained, although in an exceedingly poor yield, by careful monitoring of the concentration of ammonium sulphate against temperature. Before being exposed to X rays, all crystals were stabilized against 70% ammonium sulphate solutions. The space group is C222<sub>1</sub>, with one molecule of tRNA in the asymmetric unit. The solvent content of the crystals, ~75%, is comparable with that of the orthorhombic crystals of yeast tRNA<sup>Phe</sup>. At 20°C, the temperature at which the best crystals are grown, two crystal forms, nonisomorphous and interconvertible, are obtained.

$$\begin{array}{ll}
 a = 61.5 \text{ \AA} & a = 60.3 \text{ \AA} \\
 (A) \quad b = 67.5 \text{ \AA} & \rightleftharpoons (B) \quad b = 68.0 \text{ \AA} \\
 c = 149.5 \text{ \AA} & c = 149.5 \text{ \AA}
 \end{array}$$

The mean difference in the native  $F$  between the two crystal forms ( $\Sigma|\Delta F|/\Sigma|F|$ ) is of 15% throughout the  $\sin \theta/\lambda$  range. As it was not possible to produce selectively and identify one form or the other, two independent structure determinations had to be carried out by the MIR method. The search for the heavy-atom derivatives was hampered by the interconvertibility of the two crystal forms. For example, it was difficult to obtain a gold derivative of form A, as addition of gold salt drives crystals to an intermediate form close to that of crystals B. Experimental details are given in Fig. 2 legend.

### Electron density map

The shape and limits of the tRNA<sup>Asp</sup> molecule in the crystallographic cell could be drawn from an earlier 5-Å resolution electron-density map phased with two heavy-atom derivatives (Gd and Au, f.o.m. = 0.72). This map revealed an L-shaped structure roughly comparable with that found for tRNA<sup>Phe</sup>. Some characteristic features of the tRNA structure, like the helical stems and the anticodon loop, were clearly recognizable. The region situated near the D and TΨC stems lies close to a 2-fold axis parallel to the crystallographic direction  $a$ , which brings two molecules in close contact in that part of the cell. In this case, the problem of the boundary could be solved by topological considerations and continuity of the helices. At that resolution, however, the precise frontier between the TΨC loop and the CCA end of another molecule could not be unambiguously resolved due to the packing conditions (see below).

The 3.5-Å resolution data confirmed this first analysis and enabled us to trace the complete ribose-phosphate backbone. A few sections of the resulting electron-density map are presented in Fig. 3. Figure 3a shows a portion of the anticodon loop viewed along the direction of the  $a$  axis. Figure 3b represents part of the TΨC stem viewed down the helical stem which runs parallel with the  $a$  axis. In both, the locations of the phosphate groups are indicated by dots and correspond to bulbs of quasi-spherical electron density. A striking feature of this map is the high

**Fig. 2** Refinement statistics of form A. The diffracted intensities were collected on a four-circle Philips PW1100 diffractometer modified for protein work. Great care was taken concerning the decay of intensities in X-ray exposure, this effect being related to the Bragg angle. In standard conditions, a native crystal loses 1% of intensity per h above 3.5-Å resolution. For each crystal, data were collected in successive shells of decreasing resolution, the starting value being determined by the angle to which significant diffraction was observed. For example, for the native data of form B, six crystals were used, scaled together and merged; 5,262 independent significant reflections to 3-Å resolution were then kept, out of 17,440 observed intensities ( $F > 2\sigma F$ ), the agreement factor of intensities being equal to 5.5%. Details concerning the measurement and treatment of the data will be published elsewhere. The best heavy-atom derivative was obtained with gadolinium. The observed unicity of the binding site, when varying the Gd concentration, can be partly explained by the crystallization conditions. Lutetium and lanthane lead to similar results. Gold has two binding sites. The root mean square (r.m.s.) calculated heavy-atom structure amplitudes ( $f_H$ , continuous line) and the r.m.s. lack of closure ( $E$ , broken line) are plotted against resolution for the different isomorphous derivatives used in the refinement:  $\times$ ,  $Gd_2(SO_4)_3$ ;  $+$ ,  $Au(en)_2Cl_3$ ; and  $O$ , the mixed derivative. The distribution of the figure of merit is also indicated ( $\bullet$ ), the overall value being 0.62 for 3,477 phased reflections.

contrast between the electron density of the molecule and the solvent regions. This is even true, but to a lesser extent, for most of the loop regions which are fortunately stabilized by appropriate intermolecular contacts. Except for part of the D loop, the phosphate groups can be identified as the peaks of highest density roughly 6-Å apart. The high content of ammonium sulphate in the crystals with the resulting high ionic strength does not affect the observed signal-to-noise ratio. The background barely reaches the first countour level except in the groove formed by the T $\Psi$ C loop where a higher density can be observed which is not yet related to any molecular feature. The

electron density is also perturbed near the heavy-atom sites where ripples of negative density exist.

The very high proportion of GC base pairs in tRNA<sup>Asp</sup> probably has an important effect on the stability of the double-helical stems. This in turn is reflected in the experimental electron density. In most places the phosphate groups can be distinguished from the riboses, which appear as flat, connecting densities between the phosphate bulbs. The electron density corresponding to the paired bases can clearly be seen in the double-helical regions; this is also true for many bases of the loop regions which are probably involved in tertiary interactions, either intra- or intermolecular. This is obviously the case for the electron density associated with the T $\Psi$ C and anticodon loop regions, especially the latter which is stabilized by intermolecular contacts across a 2-fold axis. The interactions with the GUC anticodon of another molecule restrain the motion of the atoms. The resulting electron density is thus remarkably strong. At the other extremity of the map, the single-stranded CCA end is clearly visible, due to stabilizing interactions with the T $\Psi$ C loop of the neighbouring molecule. The situation is different in the region of the map corresponding to the D loop which seems weaker in both A and B forms. This was also noticed by Robertus *et al.* in the 3-Å resolution map of the monoclinic form of yeast tRNA<sup>Phe</sup> (ref. 5).

## Model

A stereo picture of a balsawood model built out of the 3.5-Å resolution electron-density map of form A is shown in Fig. 4a. This picture corresponds to a view down the crystallographic  $b$  axis. The two major structural units giving the molecule its L shape can be recognized: vertically, from the bottom, the anticodon stem followed by the D stem; horizontally, from the corner of the molecule, the T $\Psi$ C with the amino acid-accepting stem stacked on it. The molecule is approximately 20-Å thick in the viewer's direction. This model can be compared with both balsawood and space-filling models of yeast tRNA<sup>Phe</sup> (refs 19, 20). It clearly shows the more open conformation of the L in tRNA<sup>Asp</sup>, which resembles a boomerang. Two major grooves, sharply cut and without any significant electron density, can be seen in the two limbs of the molecule. These are characteristic of a RNA-type double helix.

The entire ribose-phosphate backbone of tRNA<sup>Asp</sup> deduced from the 3.5-Å resolution maps is presented in Fig. 4b in the same perspective as the balsawood model (ORTEP drawing<sup>21</sup>). The crude position of the peaks of highest density, approximately 6-Å apart from each other, was used as coordinates for the phosphate groups. The overall folding agrees with that observed for tRNA<sup>Phe</sup>. This extends the validity of the tRNA<sup>Phe</sup> model to the short-loop tRNA family and provides direct evidence that the overall folding of a tRNA remains unchanged in high (tRNA<sup>Asp</sup>) or low (tRNA<sup>Phe</sup>) salt concentrations. Even the D stem is clearly visible despite the weakness of its base pairing (two AU and two GU base pairs). This apparently contradicts

**Fig. 3** Two composites of the 3.5-Å MIR map of yeast tRNA<sup>Asp</sup>, form A. *a* Shows the electron density corresponding to part of the anticodon loop and stem (four sections between  $x = -7.7$  and  $-3.7$  Å). This region is characterized by the absence of any significant density in the major groove of the anticodon stem, and by the high electron density of the anticodon loop when compared with that of the nearby helical stem. *b* Shows densities in the amino acid acceptor- and T $\Psi$ C-stem regions (two sections between  $x = 19.4$  and  $20.7$  Å). The electron density corresponding to a Watson-Crick base pair (G6 C67) is seen between P6 and P67.

**Fig. 4** *a*, Stereo picture of a balsawood model of tRNA<sup>Asp</sup> built out of the 3.5-Å resolution electron-density map of form A. The view is down a direction roughly parallel to the crystallographic *b* axis. In that direction the thickness of the molecule is approximately 20 Å. *b*, Stereo view (ORTEP drawing) of the ribose-phosphate backbone presented in the same perspective as the balsawood model. The positions of the heavy-atom binding sites are indicated.

former NMR studies where these interactions, essentially the two AU base pairs, could not be seen in normal ionic conditions; but this is most likely related to the particular distribution of GC and AU base pairs in tRNA<sup>Asp</sup> (ref. 15).

The positions of the heavy-atom binding sites on tRNA<sup>Asp</sup> are also shown in Fig. 4*b*. The lanthanide site is situated near the position of phosphates U8 and A9. It is similar to one of the two strong samarium binding sites in yeast tRNA<sup>Phe</sup> (ref. 22). The distance between the gadolinium site and the phosphates 8 and 9 is ~4 Å; although this is not a refined value, it strongly suggests a direct interaction between the lanthanide and these phosphate groups, as observed in tRNA<sup>Phe</sup>. The fact that this is the unique marked site in tRNA<sup>Asp</sup>, whereas three other binding positions are observed in tRNA<sup>Phe</sup>, can be related to the high structural selectivity of the complexing cavity for lanthanides. In the crystallization medium of tRNA<sup>Asp</sup>, these cations have two strong competitors: magnesium and ammonium. Two possible explanations for the different behaviour of lanthanide cations observed in tRNA<sup>Asp</sup> could be the strong competition of ammonium for weak magnesium binding sites and/or a different D-loop conformation in tRNA<sup>Asp</sup> for the second, strong magnesium binding site found in tRNA<sup>Phe</sup>. Gold binds in two different sites with different affinities. The major site lies near the CCA end (phosphates C75 and A76), thus being indicative of an interaction with the phosphate group, but binding to a base of the TΨC loop of a neighbouring molecule cannot be excluded as the two parts of the molecule are close. The second gold binding site is in the pocket formed by the anticodon loop and most likely involves an attachment to the bases. Note that none

of these gold binding sites is observed in yeast tRNA<sup>Phe</sup> (ref. 23). For a mercury derivative, not used in the phasing, the heavy atom is situated on the 2-fold axis relating the anticodons of two equivalent molecules. It is a good candidate for binding to U35.

### Structural comparison with yeast tRNA<sup>Phe</sup>

Earlier attempts to solve the crystallographic structure of yeast tRNA<sup>Asp</sup> by the molecular-replacement method failed using the structure of yeast tRNA<sup>Phe</sup> as a model. Although the major peak of the rotation function was close to the best possible compromise, no reasonable solution could be obtained from the various translation functions tested. It was only after obtaining an independent chain tracing of tRNA<sup>Asp</sup> from the MIR map and having realized the close similarity of folding with that of tRNA<sup>Phe</sup> that it was possible to position roughly the tRNA<sup>Phe</sup> model in the tRNA<sup>Asp</sup> cell. A 6-Å resolution set of observed structure factors ( $F_o$ ) was then used to obtain the best fit of the two molecules by comparison with the calculated values ( $F_c$ ) derived from the tRNA<sup>Phe</sup> model. An optimization of the six parameters necessary to position the tRNA<sup>Phe</sup> model (the three eulerian rotation angles and the coordinates of the centre of mass of the molecular electron density) was carried out by minimization of  $(F_o - F_c)^2$  quantities by a least-square procedure. Convergence was slow; the reliability factor  $R = \sum \|F_o\| - \|F_c\| / \sum \|F_o\|$  decreased from 0.55 to 0.50 in 19 cycles. The high final  $R$  value for 6-Å resolution data is indicative of poor agreement between the model and the observed data. Details on these procedures will be published elsewhere.

**Fig. 5** Comparison of the ribose-phosphate backbones of yeast tRNA<sup>Asp</sup> in form A (heavy lines) with that of yeast tRNA<sup>Phe</sup> (light lines).

The resulting parameters were used to trace a superposition of the two tRNA backbones shown in Fig. 5. We recall that the tRNA<sup>Asp</sup> is an independent, unrefined model resulting from a crude positioning of phosphate groups. The first overwhelming impression concerns the similarity of the overall folding of both tRNAs. Careful inspection, however, clearly uncovers differences, but at the present level of accuracy only the major ones can be underlined. Figure 5 confirms the more open L conformation of tRNA<sup>Asp</sup>, although the superposition method tends to minimize the differences. The angle formed by the two limbs of the L is increased by more than 10° (Fig. 6). This results in different positioning of the anticodon and of the TΨC stems and loops with respect to fixed acceptor and D stems which superpose well to the corresponding parts of tRNA<sup>Phe</sup>; as a result, the D and anticodon stems are more coaxial. It is tempting to propose that conformational changes in tRNAs could result from concerted movements of the clover-leaf domains different from that suggested by the L-shaped model (see Fig. 6). A concerted behaviour of the D and acceptor stems was also suggested by thermodynamic studies<sup>14</sup> which showed that the simultaneous melting of the tertiary structure and of these two regions is the first step of denaturation of tRNA<sup>Asp</sup>.

A tilt of the anticodon stem is also observed in the initiator tRNA from yeast, but in this tRNA the angle between the acceptor and anticodon stems decreases by ~6° when compared with tRNA<sup>Phe</sup> (J. Sussmann, personal communication). A possible regulatory effect of spermine on the tilt of the anticodon stem was suggested by Quigley *et al.*<sup>24</sup> after discovery of a spermine molecule bound at the hinge region. High salt conditions might have a competitive effect which would induce a structural change at that level. However, the fact that those ionic conditions with similar spermine concentration lead to opposite changes in two different tRNAs greatly weakens such an explanation. In the variable region the deletion of one nucleotide in yeast tRNA<sup>Asp</sup> does not cause an important change. From the superposition diagram, the missing nucleotide is probably U47, which in tRNA<sup>Phe</sup> points towards the exterior of the molecule, the rest of the chain just being stretched toward C49. The resulting shift might, of course, trigger the observed tilt of the anticodon stem, thus making it a characteristic of the tRNAs with four bases in the variable region.

The relative position of the TΨC and D loops is different from that observed in tRNA<sup>Phe</sup>. The precise interactions in this part of the map are not known and further refinements are required. Nevertheless, the interaction scheme between the loops present in tRNA<sup>Phe</sup> is clearly not valid here. For example, the fact that in tRNA<sup>Asp</sup> the two conserved guanines G17 and G18 are moved in the sequence with respect to tRNA<sup>Phe</sup> makes base pairing between G18 and C56 impossible, unless the loop is shifted.

Differences exist even between the two structures of tRNA<sup>Asp</sup> corresponding to the two crystal forms by comparison of the two maps. An averaged map of the density of the two crystal forms shows a much higher contrast everywhere, except in the D-loop

region which is smeared out between nucleotides 16 and 19. This part of the molecule can be otherwise followed on each individual map. The transition between the two forms occurring around 20 °C agrees with the observed differences and stresses the mobility of the D loop. The previously mentioned thermodynamic studies imply that the observed movements of the D loop are not related to a set of especially weak interactions which loosen the structure in that region, as the acceptor stem and the D-stem helix melt simultaneously with a collapse of the tertiary structure.

## Intermolecular contacts

Three major intermolecular contacts are involved in the stabilization of the crystal packing of tRNA<sup>Asp</sup>. One contact already mentioned involves interactions between the anticodons of two molecules related by a 2-fold symmetry axis parallel to the crystallographic *b* direction. It assures the crystalline cohesion in the direction of the crystallographic *c* axis. This contact is particularly important because of the self-complementarity of the anticodon GUC of tRNA<sup>Asp</sup>. Grosjean *et al.*<sup>18</sup> have already shown that this association exists in solution. This is reflected, as shown in Fig. 3b, by a high value of the corresponding electron density which compares with that of helical regions. The comparison in that region of the tRNA<sup>Asp</sup> backbone with that of tRNA<sup>Phe</sup> in the orthorhombic form, where one anticodon is stacked on top of the other, is shown in Fig. 7a. Similar stacking interactions in tRNA<sup>Asp</sup> can be excluded by the distances between the related phosphate groups which suggest a base pairing, although the precise nature of these interactions needs a

**Fig. 6** Diagrammatic representation of the ribose-phosphate backbone and of the cloverleaf domains of tRNA<sup>Asp</sup> (indicated by different shadings). The two pointers show the more open conformation of tRNA<sup>Asp</sup> with respect to tRNA<sup>Phe</sup>. Assuming an exact superposition of the acceptor stem in the two molecules, the shift which gives the tRNA<sup>Asp</sup> molecule its boomerang shape results mainly from a different positioning of the AC and TΨC parts of the cloverleaf, the acceptor and D stems being positioned as in tRNA<sup>Phe</sup>. The arrow represents the direction of the helical axis of the anticodon stem in tRNA<sup>Phe</sup>.

**Fig. 7** Packing diagrams. *a*, Anticodon-anticodon interactions. The 2-fold axis-related backbones of the anticodon stem and loop are shown for yeast tRNA<sup>Asp</sup> (left) and for the orthorhombic form of yeast tRNA<sup>Phe</sup> (right). *b*, Partial packing diagram of yeast tRNA<sup>Asp</sup>. For clarity only four out of eight equivalent positions of the space group are traced for one and a half unit cells. The drawing shows the anticodon-anticodon contacts and the interactions between the CCA end and the TΨC loop of adjacent molecules; in the crystals this results in a network of two classes of infinite pseudo-helices, 90° apart. The crystallographic 2-fold axis relating the two anticodons is at 45° from the figure plane.

refined model. The two anticodon loops from the two strands of a double-helical structure which might represent a model of interaction between tRNA and mRNA.

Another strong intermolecular contact, introduced by the C-mode translation, involves the TΨC loop and the acceptor stem of a neighbouring molecule. This results in two infinite, kinked helices related by a dyad and 90° part. Figure 7*b* represents a partial-packing diagram, which underlines the two types of intermolecular contacts described above. A third and quantitatively important intermolecular contact is a consequence of the crystallographic 2-fold axis parallel to *c*. It brings the anticodon stem and the D stem of one molecule in close contact

with the TΨC stem of another one. In this arrangement a cage is formed by the 5' parts of the D stems of the two symmetrically related molecules. The two symmetric gadolinium atoms, 6-Å apart, enter in this cage during isomorphous substitution.

### Biological implications

The three-dimensional structure of tRNA<sup>Asp</sup> confirms the folding originally found in tRNA<sup>Phe</sup>. This result fits with an unitary structural scheme and is probably a consequence of the existence of tertiary interactions brought by the invariant and semi-invariant residues. This scheme brings together both elongator and initiator tRNAs and integrates many properties of these molecules (that is, interactions on the ribosome<sup>1,2</sup>, similar types of interaction in various tRNA-synthetase systems<sup>1</sup>, mischarging of numerous tRNAs by the same synthetase<sup>25</sup>). The tRNA<sup>Asp</sup> structure also presents differences from the canonical tRNA<sup>Phe</sup> model. With the present information, only large differences can be stressed with confidence. The most important deviations concern the respective position of the acceptor and anticodon arms of the boomerang-shaped molecule and the conformation of the loop regions. It may be asked whether the different conformation of tRNA<sup>Asp</sup> is indicative (1) of an archetype of another tRNA class or (2) of another conformation of a standard tRNA structure.

Hypothesis (1) would emphasize the structural role of the clover-leaf organization. In that case, the existing differences between the structure of tRNA<sup>Phe</sup> and the initiator tRNAs on the one hand, and the structure of tRNA<sup>Asp</sup> on the other, should result from differences in the variable loop and/or in the β region. A similar relationship between these tRNAs came out of incorrect aminoacylation studies<sup>25</sup>.

Hypothesis (2) would reflect the conformational flexibility of the tRNA molecules. Would then the conformational changes be induced by the interactions between the self-complementary anticodons, mimicking the ribosomal situation, or is it just a consequence of crystallization conditions, namely high salt concentration? The latter possibility seems to be ruled out by the results obtained with the initiator yeast tRNA<sup>Met</sup>, where similar ionic conditions lead to different structural variations. Probably the induced conformational changes and sequence-bound differences act together to give the observed structural variations. A more accurate model, as well as a detailed comparison of the two electron-density maps available, will increase our knowledge of tRNAs and help answer some of the open questions.

This work was supported by grants from the CNRS (Action Thématique Programmée: Structure Tridimensionnelle des Protéines) and DGRST. We thank M. Delfau for assistance with the purification and crystallization of tRNA<sup>Asp</sup>, M. Schlegel for help with countercurrent distribution of crude tRNA, and A. Cassou, S. Wechsler and J. Born for technical help. We also thank M. G. Rossmann for supplying the Purdue crystallographic programs from which most of the programs used in this study are adapted, A. Lifschitz for the least-square superposition, G. Quigley, N. Woo and A. Rich for discussions and programs, and D. Blow, G. Dirheimer, B. Jacrot and A. Klug for encouragement and helpful discussions.

*On the basis of their primary structure, the lysine-rich histones are a unified family of proteins. Each has an amino acid chain which falls into three distinct domains. Only the central domain (~80 residues) is in a folded conformation. It is protected from trypsin digestion in chromatin and corresponds to the segment of highest sequence conservation. Without the flanking domains it is able to close two full turns of DNA in the nucleosome and can thus locate the H1 molecule.*

THE lysine-rich histones are a group of chromosomal proteins that show considerable sequence variation when contrasted with the core histones. If calf thymus H1 is taken as the archetypal molecule, then rabbit thymus and chicken erythrocyte H1s have sequences very similar to calf<sup>1</sup>, and the trout testis H1 sequence shows only a few variations<sup>2</sup> (Fig. 1). Avian erythrocyte H5 and sea urchin sperm H1 ( $\Phi$ 1) have been considered as specialized versions of H1 but have sequences clearly related to that of calf thymus H1<sup>3-5</sup>. Recent studies of an H1 subfraction from ox liver, H1<sup>o</sup>, indicate it to be intermediate between calf thymus H1 and avian erythrocyte H5 (ref. 6). A partial sequence of an H1 molecule from somatic tissue of sea urchin<sup>7</sup> is also included in Fig. 1. The sequences of both sea urchin H1 molecules show greater homology with H5s, particularly in the central domain, than with the vertebrate H1s. On the basis of primary structure, it is clear that the lysine-rich histones are a unified family.

Studies of extracted lysine-rich histones in free solution have shown conformational homology within the family. Although fully denatured at pH 3 in the absence of salt, they can be induced to fold by increasing the pH and ionic strength, but the folded domain encompasses only a limited portion of the polypeptide chain<sup>8</sup>. For calf thymus H1 the folding domain has been defined as residues 36–121 (ref. 9). Trypsin digestion of histone H5 similarly defines residues 22–100 of that histone as containing all the secondary and tertiary structure<sup>10</sup>. Sea urchin sperm H1 also shows a trypsin-resistant peptide of approximately 80 residues<sup>11</sup>, representing the sequence 36 to about 116 (P. Sautière and P. Puigdomenech, personal communication). The finding that only a limited portion of the chain is folded and trypsin resistant could, however, be a consequence of partial denaturation on extraction and for this reason we have looked to see whether the same domain is protected from digestion in nuclei.

## Trypsin digestion of nuclei

Figure 2 shows a time course of digestion of calf thymus nuclei in isotonic conditions. The H1 subfractions are seen to be gradually degraded to a limiting peptide which runs very close to the peptide (36–121) prepared by trypsin digestion of H1 in free solution<sup>9</sup>. The two peptides have very similar amino acid analyses, and high-resolution proton-resonance spectroscopy shows that the tertiary folding of intact calf thymus H1 and both peptides are the same. We conclude that essentially the same peptide is protected from digestion in nuclei as in free solution.

Digestion experiments with proteases to probe conformation frequently show that protected and folded domains are linked by relatively short bridges of susceptible amino acid residues (hinge regions, for example, *lac* repressor). Does the H1 molecule have

only one, short, protected domain while the remainder is fully accessible to trypsin? Figure 2 shows that at early digestion times many peptides have lengths intermediate between intact H1 and the resistant peptide. The two flanking domains are clearly very accessible in chromatin and therefore probably not in a compact, folded conformation.

## Correlation of primary structure and trypsin-defined conformation

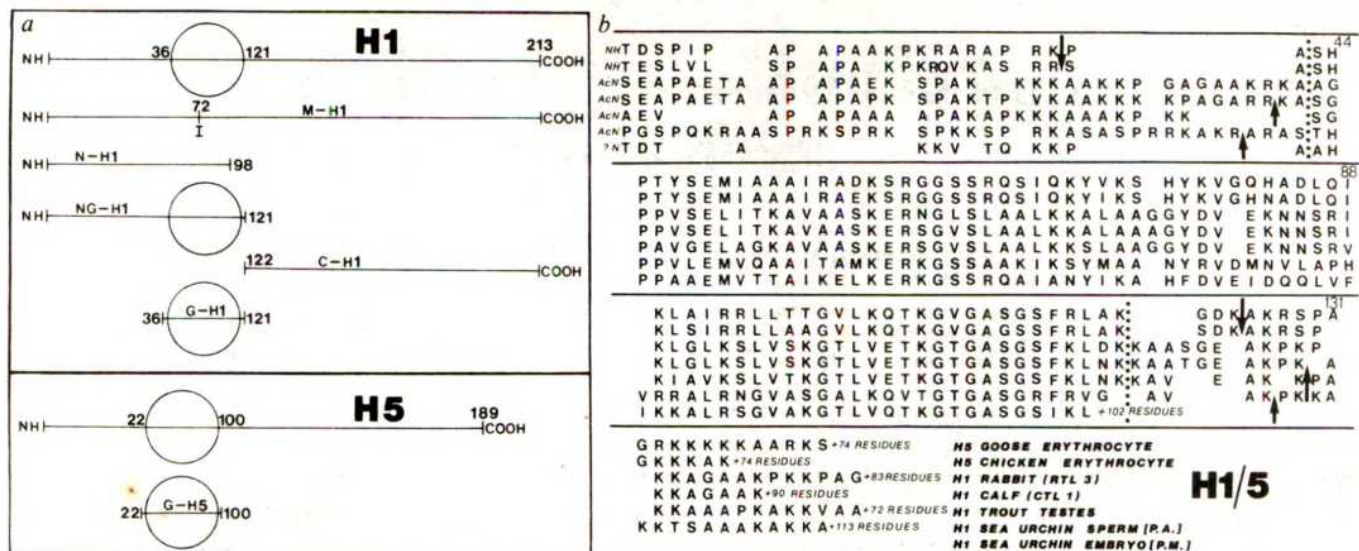

Comparison of the observed trypsin-resistant regions of three rather distant members of the H1 family with the sequence homology (Fig. 1) indicates that the protected domain coincides with the strongly conserved and more hydrophobic region of the sequence in all three cases. Although the conservation of this central domain is less than that of any of the core histones<sup>1,5,12</sup>, it is very much greater than that of the flanking domains. The N-terminal domain shows only low sequence homology throughout the family and varies greatly in length from 40 residues in sea urchin sperm to 13 residues in sea urchin embryos. Homology in the C-terminal domain is less clear-cut as in calf thymus H1, alanine + lysine + proline make up 80% of the residues. As there is considerable replacement of lysine by arginine and of alanine by serine in avian H5, some major restructuring is clearly possible in the C-terminal domain. It is clear, however, that the central, conserved sequences correspond closely with the protected peptides of calf H1, chicken H5 and sea urchin sperm H1, and homologous peptides of ~80 residues are obtained from all three proteins.

Three structural domains of H1 are therefore defined and this view of the molecule is shown in idealized form in Fig. 1. What, then, is the function and spacial arrangement of these three domains of H1 in the structure of chromatin?

## Experimental approaches to the location and function of H1

H1 has been implicated in chromatin condensation<sup>13-17</sup>. We have tested this function by preparing oligonucleosomes depleted of lysine-rich histone<sup>18</sup>. To this were reassociated peptides of H1 and the sedimentation coefficient of the reconstituted material compared with a control reconstituted with intact H1. Both reassociation and sedimentation were at 80 mM NaCl, conditions in which the extended nucleofilament is almost fully compacted into the higher-order structure<sup>17</sup>. Previous results have shown<sup>19</sup> that a ratio,  $r$ , of 2 moles of intact H1 per nucleosome is required to restore the S-value of the native chromatin and above this value extensive precipitation is

**Fig. 1** *a*, Sequences of several lysine-rich histones aligned for maximum homology. The C-terminal part, consisting largely of proline, alanine and lysine (arginine in H5s), is not fully shown. Vertical dotted lines represent the proposed limits of the strongly conserved globular domain. Bold arrows indicate tryptic cutting points in free-solution digestion of histones at high ionic strength (refs 9–11 and P. Sautière and P. Puigdomenech, personal communication). Sequences are taken from the following: goose H5, chicken H5, rabbit H1 and calf H1, trout testis H1 and sea urchin sperm H1 (*Parechinus angulosus*) (refs 3, 4, 1, 2 and 5 respectively). The sea urchin embryo H1 (*Psammechinus miliaris*) sequence is from a cloned DNA fragment<sup>7</sup>. *b*, Peptides and modified protein from calf thymus histone H1 and chicken erythrocyte H5. Calf thymus H1 was extracted with 5% perchloric acid and purified on Amberlite CG-50. It was iodinated at Tyr 72 by the addition of iodine/potassium iodide at a 1:1 molar ratio of iodine to protein in 15 mM bicarbonate buffer pH 9. The degree of iodination was determined from the NMR spectrum of tyrosine in the disordered protein and found to be 0.95 (ref. 27). NMR was also used to show that the sample of modified H1 (M-H1) does not fold<sup>27</sup>. The introduction of a very bulky atom into a buried residue<sup>35</sup> of a relatively small domain is presumed to prevent folding. The peptide N-H1 was prepared by thrombin digestion of H1 (ref. 36) and purified on CM-cellulose. Identification of the fragment was by amino acid analysis (showing the absence of phenylalanine and the presence of tyrosine), by sizing on the gel (slightly smaller than histone H4 of 102 residues) and by observing the presence of the N-terminal acetyl group in the NMR spectrum. The precise C-terminal point is not established but is  $\pm 5$  residues. The NMR spectrum of the peptide at high ionic strength indicated that it did not form a folded structure<sup>36</sup>. The peptide NG-H1 was also prepared by thrombin digestion<sup>36</sup>. The observation of perturbed peaks in the NMR spectrum of NG-H1 demonstrated that the sample used here folds to form tertiary structure. This peptide is very similar to an abundant natural degradation product of H1, previously labelled 'HMG 8' (ref. 37). We have shown by NMR spectroscopy that HMG 8 contains the folding domain of H1 and is N terminal. Peptide C-H1 was likewise prepared by thrombin digestion of H1. It does not fold<sup>36</sup>. Peptide G-H1 was made by trypsin digestion of H1 in free solution<sup>9</sup> and G-H5 likewise from chicken erythrocyte H5 (ref. 10). Both samples were checked by NMR for the ability to fold. Gel electrophoresis was used to check the purity of the peptides and proteins used.

**Fig. 2** Time course of trypsin digestion of nuclei. Triton X-100-washed calf thymus nuclei were suspended at 20 °C in 0.15 M NaCl, 10 mM Tris, pH 8, at a concentration of  $\sim 2 \text{ mg ml}^{-1}$  DNA. Trypsin was added to a molar ratio of 1:500 with respect to the content of total histone. Soybean trypsin inhibitor was added to aliquots at different times and extraction was with 5% perchloric acid. After precipitation with acetone, the proteins were analysed on 15% polyacrylamide-acid/urea gels<sup>38</sup> and compared with a sample of G-H1, the globular peptide obtained from free-solution digestion of H1 (ref. 9).

observed. Peptides were therefore reconstituted at values of  $r$  up to 2 as a test for their ability to condense the stripped chromatin. As reconstitution of H1 and its peptides results in a monotonic increase in S-value to a maximum of only 1.7 times that of the stripped chromatin, it is assumed that no interparticle cross-linking occurs.

The ability of peptides to compact the nucleofilament has also been tested by observing the rate at which micrococcal nuclease digests the linker DNA between core particles. It is known that removal of H1, with consequent breakdown of the higher-order structure, leads to an 8–10-fold increase in this rate<sup>16</sup> and H1 peptides have therefore been tested for their ability to restore the protection of linker DNA against digestion.

The location of H1 has been tested by nuclease digestion to the level of the core particle monomer. It has been proposed that the primary H1 binding site lies between 140 and 160 base pairs (the best current estimates are 146 and 165 base pairs<sup>20–22</sup>) as there is a pause in nuclease digestion at 165 base pairs and most of the H1 is lost only on subsequent trimming to 146 base pairs<sup>16,23</sup>. The best 'assay' at present for the correct location of H1 is thus the protection of 165 base pairs of DNA in the so-called chromatosome<sup>22,24,25</sup>. Although digestion of native chromatin with staphylococcal nuclease does not give 100% yields of the chromatosome before 146-base pair core particles are produced, nevertheless, if H1 is absent, no protection of 165 base pairs is observed and digestion to 146 base pairs is very much quicker<sup>16</sup>. Several peptides from H1 and H5 have therefore been reconstituted onto chromatin stripped of lysine-rich histones, and micrococcal nuclease digestion used to see whether protection of 165 base pairs is observed at a level comparable to that found in native chromatin.

## Sedimentation studies

Figure 1 shows the positions of the peptides used in the intact chains of H1 and H5. Figure 3 gives sedimentation coefficients of the reconstituted chromatin relative to the stripped chromatin used for each experiment. The results can be summarized as follows: peptide N-H1 (1-98) has no influence on the sedimentation coefficient. The peptide does however bind to the stripped chromatin as it is all found in the pellet after rapid centrifugation and NMR studies have shown that the peptide H1 (1-106) binds to DNA, albeit not strongly<sup>26</sup>. Thus, an N-terminal domain that lacks the folded central domain cannot condense the nucleofilament. Both the globular fragments G-H1 (36-121) and G-H5 (22-100) produce a small increase in S-value, but much below that of intact H1 or H5. If the N-terminal and globular domains are present together, as in the peptide NG-H1 (1-121), the increase in S-value is greater than for the globular domain alone but still only about half of that found for intact H1. When the other half of the molecule is reconstituted, that is, peptide C-H1 (122-213), the increase in S-value is only about one-third of that for intact H1, whereas if both peptides NG-H1 and C-H1 (representing the whole molecule) are reconstituted together the sedimentation increase is similar to that of either peptide alone. It is concluded that no single domain is capable of fulfilling the compacting role of H1, nor is a combination of the N-terminal and globular domains.

The C-terminal peptide, C-H1, when reconstituted for only 45 min, gives rise to an asymmetric sedimentation zone indicating a structurally heterogeneous sample, whereas after a 20-h incubation a symmetric zone was observed. The short incubation presumably results in irregular location of this peptide, although with time at 80 mM NaCl the peptide may find its correct location. Similar observations were made when the modified H1 (M-H1) was reconstituted, in that an increasingly asymmetric zone was observed as  $r$  was raised. Although at  $r = 2$  the native S-value was restored, with M-H1 the asymmetric peak was of reduced area due to loss of rapidly sedimenting material. Increased incubation time, moreover, did not yield a symmetric sedimentation peak. It is concluded that nonspecific interaction occurs between M-H1 and the stripped chromatin that involves some cross-linking between nucleofilaments and also between incorrect sites on a single nucleofilament.

## Digestion of linker DNA

Native chicken erythrocyte chromatin, or stripped chromatin reconstituted with intact calf thymus H1 or with H5 at  $r = 2$ , is about 10 times more resistant to cleavage within linker DNA than is the stripped chromatin<sup>16,18</sup> (see Fig. 4a, c). Reconstitution with iodinated H1 (M-H1) resulted in linker DNA cleavage at about the same rate as in intact chromatin (Fig. 4b). In contrast, reconstituates made from each of the peptides shown in Fig. 1 had a rate of linker digestion indistinguishable from that of stripped chromatin. It seems, therefore, that only the intact molecule can compact the nucleofilament to the degree necessary for providing linker protection.

## Monomer length fragments

Figure 5a shows that when depleted chromatin is digested with 10 times the amount of nuclease used for linker digestion, the monomer particle is trimmed essentially to a uniform length of ~146 base pairs whereas if intact H1 is reconstituted an additional product of ~168 base pairs appears as with native chromatin<sup>18</sup>. If the N-terminal fragment N-H1 (1-98) is reconstituted, only a 146-base pair band is observed, whereas if NG-H1 (1-121) is used there is considerable protection of ~168 base pairs, as in the reconstitute with intact H1. This suggests that the globular domain is essential for the protection of 168 base pairs. This was confirmed by reconstitution with the globular domain alone, G-H1 (36-121); Fig. 5b shows that, at intermediate digestion times of 2-5 min, the bands corresponding to 168 and 146 base pairs are of comparable intensity, as

**Fig. 3** Sedimentation velocity measurements of reconstituted chromatin. Chicken erythrocyte nuclei were lightly digested with micrococcal nuclease to yield chromatin of 30-50 nucleosome length. This was depleted of H1 and H5 by passage over a DNA-cellulose column at 80 mM NaCl<sup>18</sup>. Proteins and peptides were reconstituted at several values of  $r$  (mol peptide per nucleosome) by direct addition at 80 mM NaCl. The S-values of reconstituates were measured in 5-20% linear sucrose gradients together with native chromatin and H1/H5-stripped chromatin in separate buckets of the same rotor (about 99S and 58S respectively). S-values of reconstituates are expressed relative to that of stripped chromatin. The broken line in each panel represents reconstitution with intact H1 (the S-value of native chromatin is reached at about  $r = 2$  (ref. 19)). Reconstituates were annealed for 45 min except for that with C-H1 which required 20 h for a reproducible result. In the experiment involving two peptides, NG-H1 was added and annealed first and the C-H1 was added subsequently.

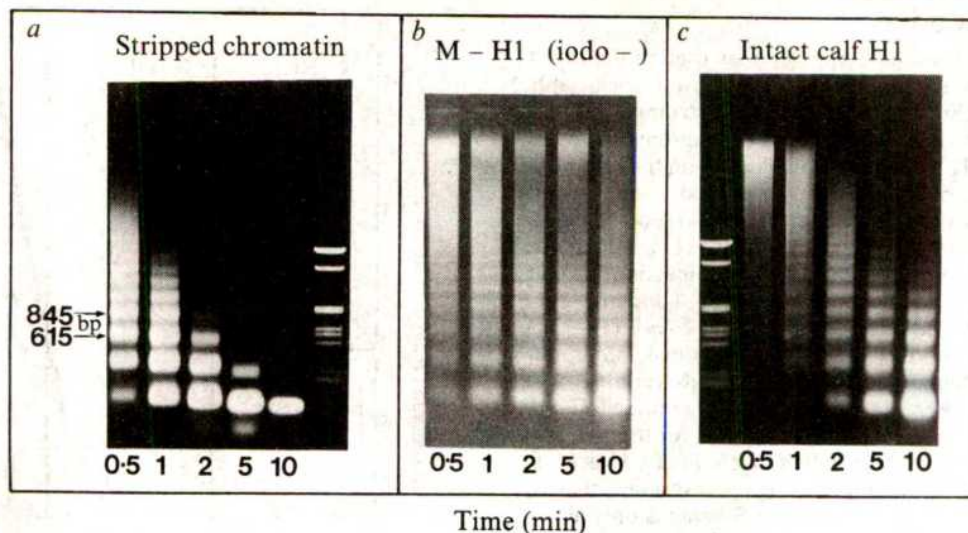

found in reconstituates with intact H1. The C-terminal half of H1 is unable to protect 168 base pairs, as shown by reconstituting with C-H1 (122-213); Fig. 5b shows no evidence of any band around 168 base pairs with this peptide. Thus, only peptides containing the central globular domain of H1 protect the 168-base pair fragment. To test that this domain must not only be present but must also be folded, a reconstitute was made with H1 iodinated at tyrosine residue 72. NMR spectroscopy has already shown that this modification is enough to prevent the molecule from folding<sup>27</sup> as the tyrosine is a buried residue. Figure 5b shows that very little protection of the 168-base pair fragment is afforded by M-H1—although there is some indication of a 10-base pair ladder at earlier digestion times (due probably to considerable compaction of the chromatin by this peptide), by 5 min there is no trace of DNA at the 168-base pair position.

The structural homology between H1 and H5 discussed above implies that the globular domain of H5 should also protect 168 base pairs. This was confirmed by reconstitution with this peptide, G-H5 (22-100). Figure 5b shows a strong and persistent band at ~168 base pairs throughout the digestion.

## Discussion

The above data indicate that: (1) a globular domain of the lysine-rich histones (~80 residues) is protected against trypsin digestion in nuclei, and (2) this domain alone can protect the

**Fig. 4** Micrococcal nuclease digestion of H1/H5-stripped chromatin and reconstitutes to show preservation of the native nucleosomal repeat and changes in the rate of digestion of linker DNA. Calibration of double-stranded DNA fragments was on 1% agarose stained with ethidium bromide using a *Hae*III digest of PM2 DNA, itself calibrated with a *Taq*I digest of  $\Phi$ X174 RF viral DNA. The DNA repeat length after stripping was  $\sim 210$  base pairs (bp). Both reconstitutes were made at 80 mM NaCl and  $r = 2$ , and the same enzyme/DNA ratio was used in all three experiments.

extra  $\sim 20$  base pairs of DNA present in the chromatosome above that in the core particle. (3) Full compaction of chromatin by H1 may require the intact molecule.

If 146 base pairs represent  $1\frac{1}{2}$  superhelical turns of DNA<sup>28</sup>, then 168 base pairs is approximately two full turns. The globular domain thus seems able to close the second integral turn of DNA. 5'-end-labelling experiments have shown that the DNA extension from core particle to chromatosome is symmetrical,  $\sim 10$  base pairs on both ends (ref. 25 and L. Lutter, personal communication), and this implies a 'symmetrical' placement of the globular domain on the 2-fold axis of the particle. Figure 6 shows a scale model of this type. Crystallographic studies of the

core particle have indicated that the pitch of the DNA is  $\sim 28$  Å (ref. 28) and this is therefore approximately the gap that would be left between the strands of DNA exiting from the particle. We have previously shown by neutron scattering<sup>10</sup> that the diameter of the globular domain of H5 (G-H5, residues 22–100) is 29 Å. (This is very close to the value of 27 Å calculated for a sphere of 79 residues with  $\bar{v} = 0.735$  ml g<sup>-1</sup>.) Recent low-angle neutron-scattering measurements on G-H1 also indicate an essentially spherical particle (J. P. Baldwin and H. W. E. Rattle, personal communication). The diameter of the globular domain is therefore very close to the pitch of the DNA and is thus consistent with the model shown in Fig. 6, in which a 'cage' of

**Fig. 5** Micrococcal nuclease digestion of stripped and reconstituted chromatins to study monomer-particle DNA lengths. Ten times the amount of enzyme was used as compared to Fig. 4. In all eight experiments the same enzyme to DNA ratio was used. Monomer DNA lengths were analysed on 6% polyacrylamide gels, stained with ethidium bromide. A *Hae*III digest of PM2 DNA was used as calibration. bp, Base pairs.

**Fig. 6** Proposed model for the location of the globular domain of the lysine-rich H1-type histones at the exit point of the 165-base pair chromatosome. bp, Base pairs.

three DNA strands is presented for binding of the globular domain.

This model is compatible with a number of reported observations. Singer and Singer have shown that H1 has a preference for super-helical DNA and have implicated the central region in this preference<sup>29</sup>. H1 may thus bind at a point of cross-over between DNA strands. Electron microscopy has shown<sup>17</sup> that only in the presence of H1 do the two DNA strands leave the core particle at the same point, that is, H1 is responsible for bringing the two strands together at exit point. In chromatosomes there is particularly strong cross-linking between H1 and both ends of the duplex DNA, and this contact between H1 and the DNA is on the opposite side of the DNA to that at which the core histones bind; that is, H1 is bound on the outside of the particle<sup>30</sup>. These data can therefore also be assimilated in the model proposed here.

The model in Fig. 6 is the most symmetrical that could be proposed and remembering the necessity for an asymmetric location of H1 (ref. 31) (and H1 is itself asymmetric), some comment is required. An asymmetric model in which 1 mole of H1 protects the extension of just 10 base pairs on one end of the core must be considered as this implies a second (equivalent) binding site giving protection of another 10 base pairs on the other end of the DNA. The existence of a second H1 binding site in the nucleosome has been proposed<sup>19,22</sup> and the precise stoichiometry of lysine-rich histone in chromatin is not yet

certain<sup>23,31-34</sup>. With such a model one would, however, expect that, at  $r=1$ , protection of predominantly a 156-base pair length would be observed, rather than ~168 base pairs, but this has not been found.

The data given above suggest that the primary function of the globular domain is to locate H1 in chromatin by closing the core particle into the chromatosome. This would be expected to involve some increase in sedimentation coefficient (Fig. 3) but does not represent full condensation of the nucleofilament. Which of the other two domains is responsible for this function? As peptide NG-H1 (1-121), which contains both the locating and the N-terminal domains, does not result in the full condensation observed with intact H1, it is concluded that the N-terminal domain is not the main agent. A fundamental structural role for the N-terminal domain is also inconsistent with the considerable sequence and length variability of this domain (Fig. 1), which rather suggests that it provides a functional distinction between different H1 species. The C-terminal domain therefore remains the most likely region for the condensation of the nucleofilament and the very basic and hydrophilic sequence of this domain fit it well for extended ionic interactions with the DNA. The present data suggest, however, that on its own it cannot achieve condensation and must be correctly located in the nucleofilament by the globular domain.

## Photon mass at low temperature?

Joel R. Primack &amp; Marc A. Sher

Physics Department, University of California, Santa Cruz, California 95064

The theoretical observation that gauge symmetries are generally restored at sufficiently high temperature has led us to consider here the conjecture that gauge symmetries are broken at sufficiently low temperature. The photon, for example, would then acquire a non-zero mass  $m_\gamma$  below some low temperature  $T_0$ . Above this phase-transition temperature, the photon would be strictly massless. Present observational limits on the photon mass show only that  $m_\gamma$  is negligible for  $T > 2.7 \text{ K} \sim 10^{-4} \text{ eV}$ . Although we have not discovered any plausible mechanism for electromagnetic gauge-symmetry breaking and therefore cannot estimate  $T_0$  or  $m_\gamma$ , there is a considerable range of experimentally accessible low temperatures for which there are no stringent constraints on  $m_\gamma$ . Non-zero gluon or graviton masses at low temperatures could also have observable consequences.

The effects of finite temperatures in gauge theories have been studied in some detail<sup>1-3</sup>. It has been shown that, in most models<sup>2,4</sup>, the gauge symmetry is restored at high temperatures, in analogy with superconductivity. In particular, in the context of grand unified theories which unify the strong, weak and electromagnetic interactions, it is now generally agreed that as we go backwards in time to the earliest moments of the big bang, as the temperature  $T$  increases, first the electro-weak  $SU(2) \times U(1)$  gauge symmetry is restored for  $T > T_1 \approx 10^2 \text{ GeV}$  and then the grand unified symmetry is restored for  $T > T_2 \approx 10^{15} \text{ GeV}$  (refs 5, 6). Above  $T_1(T_2)$ , the weak vector bosons (grand unified leptok quark bosons) are strictly massless.

The most dramatic consequence of the conjecture that all gauge symmetries are broken at sufficiently low temperatures is the breakdown of the  $U(1)$  symmetry of quantum electrodynamics (QED) at some low temperature  $T_0$ . In a detailed analysis of both terrestrial and astrophysical observations, Goldhaber and Nieto<sup>7,8</sup> deduced a very small upper limit on the photon mass,  $\sim 10^{-15} \text{ eV}$ . However, all of the observations to which they refer were performed in a heat bath of at least  $2.7 \text{ K}$  ( $\sim 10^{-4} \text{ eV}$ ), the temperature of the cosmic microwave radiation; in fact, many were done at  $\sim 300 \text{ K}$ , room temperature. If the electromagnetic gauge symmetry were broken at a temperature  $T_0$ , then any experiment done at a higher temperature would be done in a  $U(1)$ -symmetric vacuum, and the photon would be exactly massless. Thus, all of the observations considered in ref. 7 only show that  $U(1)$  is an unbroken symmetry above  $2.7 \text{ K}$ —that is  $T_0 \leq 10^{-4} \text{ eV}$ .

We know of no physical mechanism through which the electromagnetic gauge invariance could break down and the photon thereby acquire a mass. Only two mechanisms for breaking a gauge symmetry in a renormalizable way have been discovered: spontaneous and dynamical symmetry breaking. In spontaneous symmetry breaking, exemplified in solid-state physics by the Landau-Ginsburg theory of superconductivity, the photon would acquire a mass through coupling to a charged Higgs scalar field  $\phi^*$  which develops a non-zero vacuum expectation value. However, as shown in ref. 3, because the Higgs field self-coupling  $\lambda$  must be  $\leq 1$  for perturbation theory to be valid, this implies that  $m_\phi \leq 10^{-1} \text{ eV}$  for  $T \sim 300 \text{ K}$ . This is certainly inconsistent with observation, because light charged particles would be pair-produced copiously. Although heavy Higgs particles with very strong self-interactions could conceivably give rise to a phase transition in QED at low temperature, this is

not amenable to perturbative analysis nor, we believe, is it plausible.

The photon cannot acquire a mass through dynamical symmetry breaking. Dynamical symmetry breaking is exemplified in non-relativistic solid-state physics by the BCS theory of superconductivity, in which the photon acquires a mass (Meissner effect) through coupling to Cooper pairs. In relativistic dynamical symmetry breaking<sup>9</sup>, the gauge particle acquires a mass through its coupling to a bound state of a fermion-antifermion pair. This will not work for the photon because of charge conjugation ( $C$ ). A Higgs-type scalar bound state of a fermion-antifermion pair must have even  $C$  and thus could not be absorbed by the odd- $C$  photon to give the photon mass—unless  $C$  is broken in the phase transition. Stern<sup>10</sup> has also pointed out that in a massless field theory in which the coupling constant is within the domain of attraction of an IR-stable origin, there is no dynamical mass generation. Although this condition is met by conventional massless QED, its extension to finite temperature QED is not clear.

Although neither spontaneous nor dynamical symmetry breaking can give rise to a photon mass at low temperature, we regard the conjecture that gauge symmetries are broken at low temperature as sufficiently interesting to warrant experimental test, especially in view of the relative ease of such tests. The main drawback of the lack of an explicit mechanism is that we cannot estimate  $T_0$  or the photon mass,  $m_\gamma$ . The only insight we can offer on  $T_0$  is the observation that  $T \sim 1 \text{ K} \sim 10^{-4} \text{ eV}$  is about as far below the electro-weak phase transition ( $T_1 \sim 10^{11} \text{ eV}$ ) as the grand unified phase transition ( $T_2 \sim 10^{24} \text{ eV}$ ) is above it—in the logarithmic sense, relevant for the renormalization group analyses which determine  $T_1$  and  $T_2$ . Both symmetry-breaking models and physical plausibility suggest that  $m_\gamma \sim T_0$  ( $T_0$  is the only mass scale available). Lacking a specific model, we can offer no insight into the order of the phase transition; in a first (second)-order transition, the photon mass will change discontinuously (continuously) from zero as the system is cooled.

There would be many observable consequences if  $U(1)_{\text{em}}$  were broken below  $T_0$  and the photon acquired a mass  $m_\gamma$ ; we will mention two. The Poisson equation for the electrostatic potential  $V$  acquires an extra mass term

$$(\nabla^2 + m_\gamma^2)V(\mathbf{r}) = -\rho(\mathbf{r}).$$

Then the potential difference between a charged conducting sphere and an inner conducting sphere insulated from the outer one will be<sup>7</sup>

$$\frac{\Delta V}{V} = \frac{1}{2} m_\gamma^2 (a^2 - b^2) + O(m_\gamma^4 a^4)$$

where  $a$  and  $b$  are the radii of the outer and inner spheres. (Generally<sup>7</sup> the effect of  $m_\gamma$  on a system of size  $a$  is  $O(m_\gamma a^2)$ .) This effect could be detected by connecting the inner and outer spheres briefly to allow charge to flow while the system is at low temperature, and later measuring the charge on the inner sphere. A very accurate measurement of  $\Delta V$  would set stringent limits on  $m_\gamma$ , but would not be necessary to detect  $m_\gamma \sim T_0$ . A second way of detecting  $m_\gamma$  would be to measure the resonant frequencies of a superconducting cavity as a function of temperature.

Another consequence of our conjecture is that the  $SU(3)$  gauge symmetry of the strong interactions, quantum chromodynamics (QCD), is broken at low temperature. Is it possible that Fairbank *et al.*<sup>11</sup> have been the only group to detect fractionally charged particles—quarks?—because theirs has been the only low-temperature search (N. Deshpande, personal communication)?

De Rujula *et al.*<sup>12</sup> have devised an MIT-bag model of broken QCD in which the eight  $SU(3)$  gluons get equal mass  $\mu$ , and individual free quarks would have a mass  $M \sim (2\pi\alpha'\mu)^{-1}$  where

$\alpha' = 0.88 \text{ GeV}^{-2}$  is the Regge slope. Their model involves three triplets of coloured Higgs scalars, and  $\mu$  is a function of the parameters of the Higgs self-coupling potential, including the effects of gluon loops<sup>12,13</sup>. In view of the experimental lower limit on  $M$  of several GeV, they must consider  $\mu < 10 \text{ MeV}$ . (They do not discuss the behaviour of their theory as a function of temperature, although the phase transition restoring the colour gauge symmetry would be at temperatures that might be reached in extreme stellar states.)

In the model of De Rújula *et al.* there seems to be no reason why  $\mu$  could not be very small, say  $\sim 10^{-4} \text{ eV}$ . This would exemplify our conjecture: the SU(3) colour gauge symmetry would then be broken at low temperature but restored at high temperature. However, the physical consequences would at first sight seem to be negligible: although free quarks could exist, they would have large mass because of the large size  $V \sim \mu^{-1}$  of their associated colour-confining bags. The only way that light, fractionally charged particles could exist in this model would be apparently for quarks to form colourless bound states with the colour-triplet Higgs scalars. But then we do not know why this would not also happen in the unbroken phase. In any case, this is only a model—perhaps colour symmetry is broken dynamically rather than spontaneously at low temperature. As with QED, in the absence of definitive theoretical analysis we regard the low-temperature behaviour of QCD as uncertain and subject to experimental test. Other possible effects to look for at low temperature besides free quarks are slight shifts in nuclear energy levels. Unlike QED, the effects of QCD symmetry breaking at low temperature might be extremely subtle or even essentially undetectable.

Does our conjecture apply to gravitation? Although the graviton is in a limited sense a gauge particle, with the Lorentz group as the gauge group, it does not (except in non-einsteinian formulations<sup>14,15</sup>) have Yang–Mills dynamics. While several authors<sup>16,17</sup> have recently considered spontaneous symmetry breaking in the context of gravitation, their objective has been to obtain the gravitational coupling constant  $G$  through a scalar field with a nonvanishing vacuum expectation value, rather than to give the graviton a mass at low temperature. The possibility of the graviton having a non-zero rest mass at 2.7 K has been ruled out<sup>18</sup>. It would be possible in principle to observe a graviton mass experimentally, for example, by measuring the force at low temperature on a mass suspended between two unequal masses at a distance such that the force would vanish if the force law were exactly  $r^{-2}$ . If the graviton acquired a mass below some temperature which the universe eventually reaches as it expands, the cosmological consequences would obviously be profound.

One major difficulty with detecting a QCD or gravitational phase transition at low temperature should be emphasized. For a QCD phase transition to occur, it would be necessary for the coloured particles to come to thermal equilibrium with the heat bath. It is not clear that this could happen on a reasonable time scale. Because the gravitational coupling is so weak, it is even more doubtful that equilibrium could be established even on a cosmological time scale. In the case of QED, however, the presence of, for example, a charged Higgs field would lead to rapid equilibration with a photon heat bath.

We note that the simplest test of our conjecture is the measurement of the photon mass at low temperature. A positive result in such an experiment would have important consequences. One could study gauge theory symmetry breaking and phase transitions in the laboratory, the transfer of energy from the gauge boson rest mass to a cosmological constant and vice versa (that is, the apparent creation of energy discussed in ref. 3), a region of space with a different cosmological constant than in our Universe, and so on. We can offer no explanation for  $U(1)_{\text{em}}$  breaking at a low temperature, and there is also no clue as to the value of  $T_0$ . Nonetheless, we have proposed simple experiments which would at least lower the upper limit on the  $U(1)_{\text{em}}$ -breaking phase-transition temperature by a few orders of magnitude.

We thank N. Deshpande, D. Dorfan, T. Goldman, A. Guth, P. Langacker, K. T. Mahanthappa, B. Rosenblum, D. Toussaint and D. Unger, for useful discussions. This work was supported in part by the NSF.

## A study of PSR1237 + 25 at 430 MHz

T. H. Hankins

National Astronomy and Ionosphere Center, Arecibo Observatory, Arecibo, Puerto Rico 00612

G. A. E. Wright

Sonderforschungsbereich: Radioastronomie, Astronomische Institute der Universität Bonn, Auf dem Hügel 71, FRG

PSR1237 + 25, one of the first pulsars to be discovered<sup>1,2</sup>, is characterized by a striking five-peaked integrated intensity profile. Like many other pulsars, PSR1237 + 25 also exhibits the puzzling phenomena of drifting subpulses, 'nulling' and 'mode-switching'. The period of pulsation is 1.38 s, but the radio-emission occurs within an 80 ms interval. We have analysed single-pulse data from this pulsar at 430 MHz to throw light on the still obscure mechanism of pulsar emission. We conclude that the behaviour of PSR1237 + 25 can be explained on the polar-cap model if regular short (S) bursts spiralling in towards the magnetic pole are occasionally interrupted by long (L) bursts along the magnetic axis.

PSR1237 + 25 is nearby (at an estimated distance of 300 pc) and also bright (with a peak flux of 100 Jy at 430 MHz). Despite the complexity of the intensity profile, the position angle remains virtually constant during each pulse. Assuming that the radiation's plane of polarization maintains a fixed angle to the magnetic field lines, this observation is consistent with a model whereby a set of open dipolar field lines surrounding a magnetic pole is being swept perpendicularly across our line-of-sight<sup>3</sup>. Within the framework of this model the instant at which the magnetic pole is pointing directly towards us is given by the longitude at which the linear polarization disappears. We shall adopt this longitude, shown on Fig. 1 as the 'centre' of the profile.

The four principal intensity peaks (1, 2, 4, 5) of the profile can then be ordered in terms of their decreasing displacement,  $r$ , from the central longitude. The sequence obtained is  $r_1, r_5, r_2, r_4$ . The intensities  $I_1, I_5, I_2, I_4$  of the peaks follow the same sequence. Although not apparent in the time resolution of our observations (1.5 ms), component 3 may consist<sup>4</sup> of two closely-separated intensity peaks 3a and 3b.

The fluctuation spectrum of PSR1237 + 25 reveals two distinct features<sup>5</sup>. The first of these is a well-defined periodicity present in the first and fifth components and is  $\sim 2.8$  times the pulsar rotation period,  $P$  (it has been shown<sup>6</sup> that the spectra of different blocks of data show this feature to split into 2 or 3 slightly separated components). The second spectral feature is confined to the third component and is less well-defined, suggesting that it is not indicative of a strict periodicity, but

rather of a more generalized modulation time scale. This time scale is  $\sim 40P$ , or  $\sim 15$  times longer than the first feature. Component 2 may have a weak  $2.8P$ -feature, but component 4 shows no evidence of periodicity.

To see how the individual pulses give rise to these features, we have examined  $>2,000$  consecutive pulses, a typical section of which are shown in Fig. 2. The pulses have been normalized to their peak intensity with the absolute value of the peak given in flux units adjacent to each pulse; this emphasizes the changing morphology of the pulses. The periodicity of approximately three rotation periods is apparent in the first and fifth components, but in general the activity in these components is out of phase, with a peak in 1 preceding that in 5 by one period<sup>6</sup>. There is also evidence<sup>6</sup> of a lesser tendency that activity in component 2 is weak when component 1 is strong, and similarly 4 tends to be weak when 5 is strong. The result of these fluctuations is typically a cycle of approximately three periods. On average, the intensity of the first component exceeds that of the fifth component in the subsequent pulse, while in the third pulse the intensity is considerably reduced and confined to the central components. The cycle then recommences in the first component. The burst-like nature of this sequence will be referred to as an S-burst. A burst begins in the first component and subsequently subsides through the components 1-5-2-4 with the third component either quiescent or closing the burst weakly. Because the bursts last slightly less than three periods (in fact  $2.8P$ ), we gradually see them at different phases.

The simplest interpretation of these observations is that with every rotation of the neutron star the observer's beam diametrically intersects the trajectory of the S-burst in the magnetosphere, and that this trajectory is a spiral (Fig. 3). Although our choice for its sense is arbitrary, clearly the burst must begin in such a way that it first intersects the path of the observer's beam at the longitude of the first component. It then proceeds to describe a spiral with diminishing intensity through the components 5, 2, 4 and, possibly, 3a and 3b. It is also clear from inspection of the individual pulses (see Fig. 2) that in any given pulse emission is often simultaneously present in several components, suggesting that as it moves towards the centre the burst becomes linearly extended along its trajectory.

Fig. 1 Integrated polarization profile of 1,593 pulses at 430 MHz, showing the five labelled pulse components. Linear and circular polarization are shown by a light line and a line with small circles, respectively. The linear polarization angle is depicted by the dotted line and the ratio  $V/P$  where  $P = (Q^2 + U^2 + V^2)^{1/2}$  is shown by the lower light line. The 'central' longitude is chosen as the point where linear polarization is a minimum, circular is a maximum, and the position angle is discontinuous.

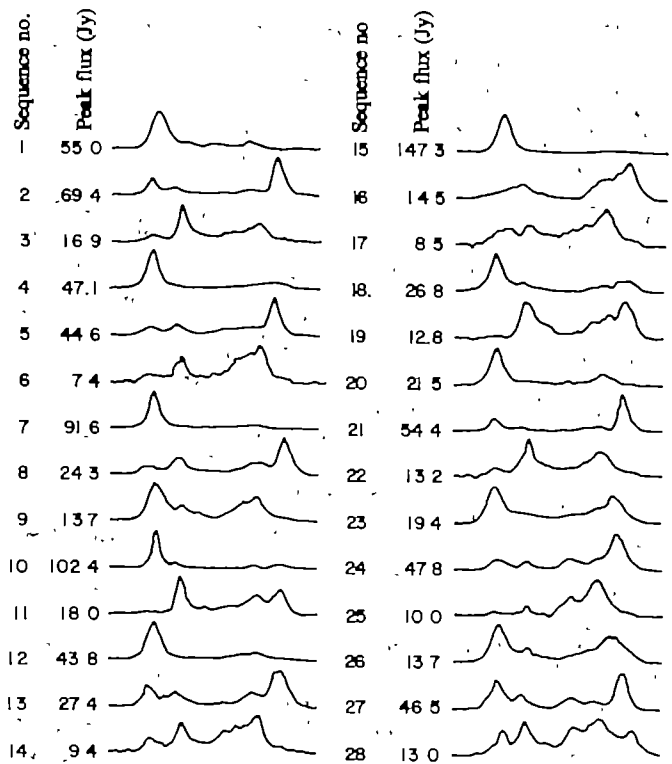

Fig. 2 28 consecutive pulses showing 10 complete S-bursts

Frequently, the burst recommences in component 1 before the previous burst has completely faded from the central components.

Interpreting the succession of the four principal components (1, 5, 2, 4) as successive increases in angular units of  $\pi$  ( $0, \pi, 2\pi, 3\pi$ ), we have plotted in Fig. 4 the natural logarithm of the components' displacements from the central longitude against this angle ( $r$  being normalized by  $r_1$ ). The result is approximately a straight line. This suggests that the burst moves along a logarithmic (or equiangular) spiral whose radius decreases exponentially with angle. Such spirals are described by the equation  $r = r_1 \exp(-\theta \cot \alpha)$ .

Two of the geometric properties of this spiral are of interest: first, its tangent (and hence the trajectory of the burst) makes a constant angle  $\alpha$  with the radius vector. Second, the intersections of any radius vector with successive turns of the spiral form a geometric progression whose common ratio  $k$  is related to the angle  $\alpha$  by  $k = \exp(2\pi \cot \alpha)$ . The straight line in Fig. 4, to which the peaks of the profile closely conform, implies a spiral with  $k \approx 1.62$  and a corresponding angle  $\alpha = 85.5^\circ$ . It may only be coincidence that equiangular spirals are also formed by the shells of *Nautilus Pompilius*<sup>7,8</sup> and other gastropods,  $85^\circ$  being a typical value for their determining angle.

The S-bursts do not, however, repeat indefinitely. At irregular intervals of  $\sim 40$  pulses (or 15 S-bursts) independent activity begins close to the central longitude of the profile (in the third component). This is sometimes, though not always, accompanied by 'nulling', whereby no emission is detected above the noise level ( $0.5$  Jy) for several successive pulses. Among the 2,100 pulses we have inspected there are 22 stretches of sustained nulls (that is, no emission was detected in two or more consecutive pulses, implying that the intrinsic lifetime of the nulls was at least a full rotation period). In every case, the pulses following the nulls showed activity in the third component and in 40% of the cases the nulls were also preceded by such activity (a third component-null association was also noted in the early work of Backer<sup>1</sup>). These 'eruptions' in the third component will be referred to as L-bursts.

Is the  $2.8P$  periodicity 'remembered' during an L-burst so that the S-bursts restart in phase? The splitting of the  $2.8P$  line in the fluctuation spectrum, referred to earlier<sup>2</sup>, is what would be expected of the phase were 'forgotten'. The phase may be lost

during every L-burst or, less frequently, during a null sequence. The amount of splitting would, therefore, depend on the number of L-bursts or nulls included in the data blocks. It may be possible to examine this hypothesis by eliminating nulls and/or L-bursts from the data and re-determining the fluctuation spectrum. This might bring the S-bursts back into phase and make the 2.8P feature free of splitting and broadening. This effect has already been found<sup>11</sup> in PSR0809+74, a pulsar of similar age and period, where nulls occasionally interrupt a highly regular subpulse drift: the nulls sever the drift-bands so that only by removing them from the data is the continuity of the drift restored.

In common with PSR0329+54 and possibly other pulsars, PSR1237+25 switches occasionally into an 'abnormal' mode<sup>2,12-14</sup>, whereby the emission pattern is radically changed. Only one example of this mode occurred in our data, lasting 74 pulses, but unfortunately at a time when interstellar scintillation weakened the definition of the pulses. There is considerable similarity between abnormal mode activity and that observed during the L-bursts. The mode is characterized by sustained activity in the third component and by changes in the longitude of the outer components. No S-burst periodicity can be seen, and we can again only suggest that their repetition has either become irregular or now has a time scale comparable to the rotation period. At our observing frequency (430 MHz) the components in the left hand of the profile are considerably stronger than those on the right: a feature which may be the result of longitudinally-dependent propagation effects.

The polar cap model<sup>15-18</sup> is still the only model which offers a physical explanation for the drift behaviour of sub-pulses. It postulates the existence of a 100-m diameter cap surrounding the magnetic pole on the neutron star's surface, whose outer limits are determined by the last magnetic field lines to close within the light-cylinder. Above the cap a gap of height 100 m forms, in which strong electric fields are maintained both parallel and perpendicular to the magnetic field. Within this volume  $\gamma$  rays with sufficient photon momentum perpendicular to the magnetic field (originating either from the hot surface or

Fig. 3 The proposed spiral path of the S-burst around the magnetic pole and its relation to the observed intensity peaks. The path of the observer's line of sight is shown passing directly over the magnetic pole.

Fig. 4 Plot of  $\ln(r/r_1)$  against  $\theta$ . The straight line corresponds to a logarithmic spiral with a common ratio of  $k = 1.62$ .

from strongly-accelerated particles) generate cascades of electron-positron pairs. These particles are accelerated outwards and, following further pair-creation, excite two-stream instabilities which generate the observed coherent radiation in the upper magnetosphere ( $10^7$ – $10^8$  cm above the cap in the most recent version<sup>17</sup> of the model).

Ruderman and Sutherland<sup>16</sup> have suggested that the drift of sparks around the magnetic pole is the consequence of deviation in the local electric field from its 'force-free' value. The sparks are likely to arise near the edges of the cap where the field-line curvature is largest (and, therefore, where the probability of pair-creation is greatest<sup>19</sup>). Assuming the trajectories to be circles, they arrive at the expression  $5.6B_{12}/P^2$  for the circulation period of the single spark region in units of  $P$  ( $B_{12}$  being the magnetic field strength in  $10^{12}$  G). Inserting the appropriate parameters for PSR1237+25 we obtain a value of  $2.9P$  for the drift period, in close agreement with the observed periodicity of  $2.8P$  for the S-bursts. Ruderman and Sutherland do not discuss the possibility of non-circular drifting, but for an  $85.5^\circ$  spiral the inward radial velocity will only be a fraction  $\cot 85.5^\circ = 0.08$  of the tangential velocity and so in a sense only a second-order effect. No obvious explanation is available for the radial drift: possibly the sparking region, having circumscribed the pole is then for some reason inhibited from repeating its trajectory and moves to an inner radius. Note that a spark following the spiral of Fig. 3 would exploit the entire surface of the cap. Alternatively, we might argue that the presence of the spark will itself distort the electric potential from its axisymmetric form (as pointed out by Jones<sup>18</sup>). There is then no reason to expect the drift trajectory to be perpendicular to the radius. It is also difficult to explain why the inner radius of the sparking region does not move to the pole within milliseconds if the cascade mechanism described by Sturrock<sup>15</sup> is operating. Radial confinement of the spark may be more easily achieved if pair-creation is being sustained by the 'photon splash'<sup>17,18</sup> of  $\gamma$  rays from the surface of the cap.

The simultaneous appearance of the S-bursts in several components suggests that the burst becomes linearly extended along its path. This would occur, for example, if a spark of finite angular size were to drift along a spiral with an angular velocity which increased towards its centre. Constant lateral drift velocity is one, but not the only, possibility. The angular velocity would then increase proportionately with each turn.

The behaviour of the L-bursts cannot be explained on any current theory. Their association with nulling and their modulating effect on the S-bursts suggest that an understanding of their role is crucial. Possibly the S-bursts represent charging and L-bursts discharging of the neutron star. The third component of PSR1237+25 may require a separate physical explanation<sup>10,14</sup>. Perhaps this is a hint as to why in most pulsars nulls interrupt the pulse trains in such an apparently random way<sup>20</sup>: if PSR1237+25 were viewed from any angle other than that which contains the magnetic axis, then the subpulse drift and the

nulling would still be observed, but not the third component. Although a null involves the entire polar cap, its causal mechanism may be confined to the centre and, therefore, seldom seen. Interestingly, in several pulsars Backer<sup>5</sup> has found modulations of typically 100 periods in addition to the short-term drift periodicities. Their possible connection with nulls does not seem to have been investigated.

Multiply-peaked integrated profiles are not uncommon among pulsars<sup>10</sup>, often with asymmetrically distributed peaks. PSR0329+54 and PSR2045-16 are perhaps the best and brightest examples. Intriguingly the binary pulsar<sup>21</sup>, whose individual pulses are too faint to detect, has also an asymmetric triple peak profile. It would, however, be rash to extend the present model to other pulsars without further investigation. The pulsars still have much to teach us, and have hidden their secrets well.

We thank N. Bartel, W. Fawley, L. Fowler, D. Morris and W. Sieber for helpful discussions, and J. M. Rankin for development of the polarization measurement and reduction system at Arecibo. G.A.E.W. thanks the Sonderforschungsbereich: Radioastronomie for support. Much of this work was done while T.H.H. was visiting Max-Planck Institute for Radioastronomy supported by a fellowship from the Alexander von Humboldt Stiftung.

## Unambiguous mass determination of major stratospheric positive ions

E. Arijs, D. Nevejans & J. Ingels

Belgian Institute for Space Aeronomy, Ringlaan 3, B-1180 Brussels, Belgium

There has been recent considerable interest in the stratospheric ion composition and ion chemistry, especially in view of its possible impact on aerosol formation<sup>1,2</sup> and the possibility of detection of minor constituents with very low concentrations<sup>3,4</sup>. The first composition measurements of positive ions in the stratosphere conducted by a rocket-borne instrument<sup>5</sup>, revealed the existence of the theoretically predicted proton hydrates (PH)<sup>6</sup> and also of some unexpected non-proton hydrates (NPH). (Proton hydrates are primarily ions of the form  $H^+(H_2O)_n$ ). Because low altitude rocket data may be biased by shock wave effects, such as ion fragmentation, the need for balloon flights was strongly felt. In 1978, data obtained with balloon-borne instruments<sup>7-9</sup> partly confirmed and extended the rocket data. There have been several explanations<sup>1,5,7,8,10</sup> of the presence of the observed NPH, but the lack of resolution of the data means an ambiguity still exists about the exact masses of these ions. We report here the first high resolution mass spectra of positive ions in the stratosphere, at 34-km altitude, where the major mass peaks can be identified unambiguously.

The data were obtained with a balloon-borne mass spectrometer, flown on 16 June 1980 with a 100,000 m<sup>3</sup> stratospheric balloon at mid-latitude (CNES launching base at Gap-Tallard, France, 44°33'N). The instrument was launched at 20.38 UT and reached float altitude (34 km) at 22.50 UT, time at which the measurements were started. The flight lasted 8 h and thus mass spectra were obtained in both night-time and day-time conditions. Both positive and negative ions were observed. All measurements were performed at float altitude.

We concentrate here on the masses of the most abundant positive ions during night-time. The data on negative ions will be reported elsewhere.

The instrument primarily consists of a high speed cryopump, described in detail elsewhere<sup>11</sup>, in which a quadrupole mass filter is built and of the associated electronics. The stratospheric ions are sampled through a small orifice (0.2 mm diameter), drilled into a thin stainless steel flange, which can be biased with respect to the gondola (draw-in potential). They are focused into the quadrupole by an electrostatic lens. After mass filtering they reach a high gain electron multiplier, the signals of which are treated by pulse counting techniques. Between the inlet aperture and the mass filter an electron impact ion source is incorporated into the lens system. It can be put on and off by remote control and enables us to analyse the residual gas in the cryopump. Simultaneously a gas mixture of argon, krypton and xenon is injected into the mass spectrometer and an in-flight mass scale calibration is performed, using the well known mass numbers of the different Ar-Kr-Xe isotopes.

The mass spectrometer covers the mass range 0-330 AMU (at high resolution) and is microprocessor controlled. This produces a very flexible system. Several modes of operation can be called on, such as positive ion sampling, negative ion sampling and the neutral or calibration mode. The mass spectra are scanned either with a constant resolution or with a constant peak width. Most of the data for positive ions were obtained with a constant peak width ( $\Delta m$ ) of 0.9 AMU at FWHM. A higher resolution setting implies a lower transmission of the quadrupole mass filter<sup>12</sup>. Because in the constant peak width mode the resolution ( $m/\Delta m$ ) is increasing with increasing mass number ( $m$ ), the transmission of the instrument will be strongly decreased at higher mass numbers. Therefore very few counts have been observed above mass 119 in the positive ion sampling mode.

Figures 1 and 2 show typical spectra, obtained in the mass domains 50-106 and 90-146 AMU respectively. The corresponding calibration spectra produced in flight are also shown. With such spectra, obtained in different mass domains, the major ion mass peaks could be identified unambiguously after the appropriate integration time. The observed mass peaks, fitting into the formerly observed PH and NPH schemes are summarized in Table 1 together with their identification.

Mass 60 is a minor peak and is not shown in Fig. 1. It has only been observed after long integration times in a small mass domain (53-63 AMU), but it is added to Table 1 for completeness.

From Table 1, two ion series can be clearly distinguished. The first series, containing masses 55, 73 and 91 can be identified as

**Table 1** Major observed positive ion mass peaks during night-time at 34 km

| Mass number (AMU) | Identification<br>X = 41 AMU | Observed count rate<br>(mean value<br>counts per s) |
|-------------------|------------------------------|---|
| 55                | $H_3O^+(H_2O)_2$             | 3.7   |
| 60                | $HX^+(H_2O)$                 |   |
| 73                | $H_3O^+(H_2O)_3$             | 20.0  |
| 78                | $HX^+(H_2O)_2$               | 5.7   |
| 91                | $H_3O^+(H_2O)_4$             | 1.9   |
| 96                | $HX^+(H_2O)_3$               | 30.0  |
| 101               | $HX^+X(H_2O)$                | 2.4   |
| 114               | $HX^+(H_2O)_4$               | 0.6   |
| 119               | $HX^+X(H_2O)_2$              | 3.3   |

PH with the general formula  $\text{H}_3\text{O}^+ \cdot n\text{H}_2\text{O}$ . As can be expected from the thermochemical data on water ion clustering<sup>13,14</sup> mass 73 is the most abundant peak among the PH. The existence of major masses, fitting the formula  $\text{NH}_4^+ \cdot n\text{NH}_3 \cdot m\text{H}_2\text{O}$  can now be excluded from the present high resolution spectra. This confirms the conclusions about  $\text{NH}_3$  playing no significant part in the stratospheric ion chemistry at 34 km altitude<sup>8</sup>.

A second distinct ion sequence is the one containing masses 60, 78, 96, 114 and 119 AMU. It is generally accepted that these ions are the result of a reaction of the PH with an unknown trace gas X. As was suggested by the Heidelberg group<sup>8</sup> the formula of these NPH has the general form  $\text{XH}^+ \cdot n\text{X} \cdot m\text{H}_2\text{O}$ . Up to now, however, there has been ambiguity about the exact mass number of X and the best information available so far was  $41 \pm 1$  AMU.

Although Arnold *et al.*<sup>5</sup> at first proposed that formaldehyde was responsible for the presence of NPH in the stratosphere, this theory was rejected after laboratory measurements<sup>15</sup>. More recently, these authors<sup>8</sup> concluded from the measured relative abundances of the PH and NPH that X must have a number density of the order of  $10^5 \text{ cm}^{-3}$  at 36 km and a proton affinity larger than  $175 \text{ kcal mol}^{-1}$ . Consequently they suggested  $\text{CH}_3\text{CN}$  (acetonitrile) as a possible candidate for X.

The fact that no formation mechanism for  $\text{CH}_3\text{CN}$  in the stratosphere was known led Ferguson to the NaOH proposal<sup>1</sup>. The existence of the sodium layer in the atmosphere<sup>16</sup> made this hypothesis quite plausible. The proposal even received support from model calculations<sup>17</sup> and laboratory work<sup>18</sup>. Recently, however, attention has been drawn to some loss mechanisms for NaOH in the stratosphere<sup>10</sup> and MgOH was suggested as a new candidate for X. However, the exact mass, as well as the identity of X has remained an open question.

The most important conclusion, which can be drawn immediately from our data, is that the mass number of the so far unknown molecule X is 41 AMU. Although mass 42 ( $\text{HX}^+$ ) has not been observed, the presence of mass 101 and 119 can only be explained by putting the mass of  $\text{X} = 41$  AMU. The conclusion rules out the hypothesis of X being NaOH (at least during night-time). The other suggestion that X might be solely MgOH is very unlikely. Actually if this were the case, one should

**Fig. 1** *a*, Typical pre-sunrise spectrum obtained in the mass region 50–106 AMU after 14 scans. Each mass unit is divided into six channels. Dwell time per channel, 0.25 s. Duration of one scan, 84 s;  $\Delta m = 0.9$  AMU FWHM. *b*, In-flight calibration obtained in the same mass domain with krypton isotopes. Only one scan is performed here.

**Fig. 2** *a*, Night-time spectrum in the mass region 90–146 AMU. Number of scans is 42. Programmed  $\Delta m = 0.9$  AMU. Real  $\Delta m$  is larger in this domain. *b*, Mass scale calibration performed in flight in the same mass domain with xenon isotopes. Result of one scan.

measure a count rate at masses 97 and 98 of  $\sim 13\%$  of that observed at mass 96, due to the isotopic abundances of  $^{25}\text{Mg}$  and  $^{26}\text{Mg}$ . This is, as Fig. 1 shows, not the case. Nevertheless, the possibility of a small contribution of MgOH to the NPH peaks cannot be ruled out completely; this will have to await high resolution data with large accumulated ion count numbers.

Most of the NPH peaks originate from a molecule with mass 41, different from MgOH. So far the most likely candidate for this molecule seems to be acetonitrile ( $\text{CH}_3\text{CN}$ ), which has a higher proton affinity than water (187.4 kcal compared with 168.9 kcal for  $\text{H}_2\text{O}$ ) (ref. 19) as well as a higher dipole moment (3.92 db compared with 1.85 db for  $\text{H}_2\text{O}$ ) (ref. 20). Although no production mechanism is known for  $\text{CH}_3\text{CN}$  in the stratosphere only a very low concentration ( $10^5 \text{ cm}^{-3}$ ) is required to explain the conversion from PH to NPH. In this framework a critical investigation of some neutral reactions, such as those of active nitrogen (especially in excited states), which can be produced by cosmic rays<sup>21</sup>, with  $\text{CH}_4$ , as well as ion molecule reactions of  $\text{N}^+$  and  $\text{N}_3^+$  with  $\text{CH}_4$  (ref. 22) might be useful to look for a possible source of  $\text{CH}_3\text{CN}$  in the stratosphere. Furthermore the possibility that  $\text{CH}_3\text{CN}$  (which has been observed in interstellar clouds)<sup>23</sup> originates from cosmic dust cannot be overlooked.

Note that no reaction rate coefficients for the ion molecule reaction of PH with  $\text{CH}_3\text{CN}$  have been published. Although they are exothermal and are, therefore, expected to have a large rate coefficient, the study of such reactions at the appropriate temperature is strongly recommended. Up to now, however, the only certain fact about X is its mass number and even the identification of X as acetonitrile remains speculative.

Apart from the masses listed in Table 1, a peak is observed in Fig. 2, which corresponds to 117 AMU. Although this mass can be explained by the ion  $\text{NaOH}_2^+ \cdot \text{NaOH} \cdot 2\text{H}_2\text{O}$ , it is very unlikely that it originates from NaOH because at night the other peaks of the series  $\text{NaOH}_2^+ \cdot n\text{NaOH} \cdot m\text{H}_2\text{O}$  are not observed. It is, therefore, more probable that this peak belongs to a third series  $\text{YH}^+ \cdot n\text{Y} \cdot m\text{H}_2\text{O}$ . The analysis of the minor peaks indicates the existence of other members of this family. However, a more detailed analysis of the present data, as well as high resolution mass spectra with long integration times are needed to identify this series.

Finally, note that the present data are only representative of the night-time ion chemistry at 34-km altitude and that more *in situ* measurements are needed to generalize the conclusions.

We thank the technical staff of the Belgian Institute for Aeronomy and the CNES for the enthusiastic cooperation during the realization of the instrument and the balloon flight. We are also indebted to the NFWO (Belgian National Science Foundation) for partly financing this project.

## Carbon deposition on metallic surfaces studied by r.f. plasma discharge

J. A. Cairns, J. P. Coad, E. W. T. Richards  
& I. A. Stenhouse

AERE Harwell, Didcot, Oxfordshire OX11 0RA, UK

The accumulation of carbonaceous deposits on surfaces exposed to gases containing hydrocarbons or carbon monoxide is an undesirable phenomenon which can cause contamination of, for example, steel containment vessels and catalyst surfaces. It has been found<sup>1</sup> to occur also in certain conditions on the steel fuel pins of the Advanced Gas Cooled Reactor (AGR). Although in this instance it can be prevented by controlling the coolant composition, there is a strong motivation to understand the basic mechanisms involved. We show here, principally by means of a radio-frequency (r.f.) plasma-discharge system incorporating spectrographic analysis, that the deposits are formed largely as a result of the catalytic activities of the exposed surfaces (even here in the presence of highly ionized gases) and that deposition can be prevented by suitable coatings. These findings have now been confirmed by in-reactor experiments.

Whenever hydrocarbon molecules come into contact with metal surfaces, they exhibit a finite tendency to deposit carbonaceous material. This tendency depends on the chemical nature of the hydrocarbon. (For example, unsaturated molecules are particularly prone to such behaviour.) One example of this effect is the tendency for carbonaceous material to deposit on to the surfaces of the stainless steel fuel pins in an AGR. These fuel pins, which are manufactured from 20%Cr/25%Ni/Nb stabilized steel (20/25/Nb steel) are designed to operate within a temperature range 350-750°C and be subjected to a coolant

which consists mainly of CO<sub>2</sub>, but also contains significant concentrations of CO (a few per cent) and CH<sub>4</sub> (a few hundred p.p.m. by volume). The latter component was specified to suppress any tendency for the CO<sub>2</sub> to oxidize the graphite moderator<sup>2</sup>. Although carbonaceous deposition can be prevented in practice by choosing specific levels of CO and CH<sub>4</sub> additions, it remains important to understand the basic reasons for its formation. The environment within which these events take place, namely the core of a nuclear reactor, renders direct observation very difficult, and subsequent examination of steel specimens exposed to the reactor flux is complicated by their induced radioactivity.

We have subjected specimens of the steel to an r.f. plasma discharge of a CO<sub>2</sub>/CH<sub>4</sub> gas, thereby providing an irradiation environment free from the problems of induced radioactivity. It then becomes possible to compare in laboratory conditions the amounts of carbonaceous material deposited on the steel to that deposited on other surfaces, particularly copper, which has been observed<sup>3</sup> to remain clean in reactor conditions.

Fig. 1 Experimental arrangement showing specimens suspended in a CH<sub>4</sub>/CO<sub>2</sub> r.f. plasma discharge.

Figure 1 shows the r.f. equipment in operation. Sections of AGR 20/25/Nb steel tubing (15-mm diameter) were mounted in the middle of a silica tube, surrounded by flowing gas at a pressure of 4.7 mbar and subjected to a r.f. plasma discharge (2kV; 2.5 MHz). The gas used was an equivolume CO<sub>2</sub>/CH<sub>4</sub> mixture. This methane level is, of course, much higher than that present in an AGR but it was necessary here to counteract the enhanced oxidative capacity of the CO<sub>2</sub> induced by the intense field. In spite of this, the main effects observed previously in AGR were reproduced. Thus the steel acquired a significant deposit of carbon (0.2-0.5 mg cm<sup>-2</sup>) after 4 h, whereas speci-

mens of copper mounted alongside the steel remained essentially clean. Incidentally the carbon was measured by combustion in a Leco CS 144 carbon/sulphur analyser and determined as  $\text{CO}_2$  using IR detection.

The above measurements on copper and steel indicate a clear influence of the surface chemistry of the steel in promoting deposition. To nullify this surface activity and thereby suppress the deposition, the steel was coated with a silica layer (1–2- $\mu\text{m}$  thick). A convenient method is to contact the steel with a silica sol, which on heating (to 850 °C for 15 min) densifies to form a dense, protective silica coating<sup>4</sup>. The result was dramatic: the silica-coated steel remained clean throughout its exposure to the  $\text{CO}_2/\text{CH}_4$  discharge, as may be confirmed from Fig. 2 which shows also that nearby uncoated steel specimens acquired carbonaceous deposits. These visual observations were supplemented by carbon analysis, which confirmed that the silica-coated specimen had acquired a negligible amount of deposit. We now consider why the silica-coated specimen remained uncontaminated: was it due to carbonaceous material being removed dynamically with enhanced efficiency throughout the exposure, or was it due to the fact that the silica surface was unable to induce deposition from its surrounding gas, even in the presence of the ionizing environment? The answer can be found by a spectroscopic examination of the light emitted from the plasma, particularly in the vicinity of the specimens.

Light emitted from a 5-cm long section of the discharge was imaged on to the slit of a Hilger medium quartz spectrograph. It was thereby possible to compare the relative emission intensities of individual spectral lines to the region from which they arose in the plasma. Identification of spectral lines and variations in these, as compared with a standard  $\text{CO}_2$  discharge, was done using a Hilger projection comparator. A comparison between some of the species present in the vicinity of a 20/25/Nb steel surface and a corresponding silica-coated specimen, during exposure to an equivolume  $\text{CO}_2/\text{CH}_4$  discharge, is shown in Table 1.

When the gas remote from the sample was examined for these species, it was found to contain principally  $\text{CH}$ ,  $\text{H}$  and  $\text{CO}^+$ , although the signal strengths were lower than in the highly ionized region near the specimens. Of particular interest are the strong signals in the vicinity of the uncoated steel of  $\text{CO}^+$  and  $\text{O}_2^+$ . Both of these were very weak or not detected in the bulk of the plasma or, as seen from Table 1, in the vicinity of the coated steel. Therefore it may be deduced that methane tends to suppress  $\text{O}_2^+$  by gas-phase interaction. It seems reasonable to suggest further that methane is removed dynamically in the vicinity of the uncoated steel (hence the reappearance of  $\text{O}_2^+$ ), being converted under the catalytic influence of the steel's surface to a carbonaceous deposit. This in turn is subject to attack by the oxidizing species, thereby accounting, at least partly, for the appearance there of the strong  $\text{CO}^+$  signal. The lack of carbonaceous deposition on to the silica-coated steel specimen can be understood also: the silica surface, being free from sites which catalyse deposition, remains essentially clean and so there is little  $\text{CO}^+$  production. The  $\text{O}_2^+$  signal is low because the local concentration of methane is retained.

Therefore, the results suggest that carbonaceous deposition on to the steel surface is induced largely by the catalytic activity

**Fig. 2** The reduction in carbonaceous deposition exhibited by a silica-coated steel tube section as compared with nearby, uncoated specimens.

of the surface itself. Surfaces such as silica remain clean because they do not intervene to alter the gas composition in their immediate environment.

The r.f. plasma-discharge system used here has not only highlighted the importance of coatings to prevent carbonaceous deposition, but may be used also to screen suitable coatings for in-reactor assessment. The best coatings identified by this screening have been confirmed to perform well in nuclear reactor conditions.

Finally, there is much scientific literature on the nature of species formed as a result of ionization of  $\text{CO}_2$  and of  $\text{CO}_2/\text{CH}_4$  (ref. 5). However, the main difference between those studies and the present one is that here we emphasize the influence of surfaces, and particularly the 20/25/Nb steel surface in promoting carbonaceous deposition. We cannot be certain that the species identified here at low pressure will exist in that form at AGR pressures and, of course, the composition of the plasma gas examined here differs substantially from that of a genuine AGR coolant. We can conclude, however, that the success in reproducing some of the more significant gas–solid interactions indicates a general validity to the conclusions which have been reached so far.

## Generation of light hydrocarbons in sedimentary rocks

J. M. Hunt\*, A. Y. Huc† & J. K. Whelan\*

† Laboratoire de Géologie Appliquée, CNRS-ERA 601, Université d'Orléans, 45046 Orléans Cedex, France

Most petroleum arises from the thermal alteration of organic matter in fine-grained sedimentary rocks. The time-temperature conditions of petroleum formation have been defined by numerous laboratory and field studies<sup>1</sup>, but little is known of the conditions in which individual hydrocarbons form in nature. The light hydrocarbons are of particular interest because they are present only in traces in surface sediments, yet they constitute about 30% of a typical petroleum. We have found that the distribution of individual  $C_6$ – $C_8$  hydrocarbons in shale samples from a Gulf of Mexico well indicates that different types of structures are being generated preferentially at different depths. Hydrocarbons with a tertiary carbon atom apparently formed earlier than those with a quaternary carbon because of the greater stability of the intermediate tertiary carbonium ion or free radical.

The samples analysed were well cuttings from a Coastal Offshore Stratigraphic Test (COST) well drilled by a consortium of oil companies about 50 miles east of South Padre Island, off south Texas in the Gulf of Mexico. The cuttings were washed, canned at the well site and kept refrigerated. At the laboratory the drilling mud was washed from the cuttings before analysis.

The  $C_6$ – $C_8$  hydrocarbons were analysed by a headspace method involving the grinding of the cuttings in a closed container and release of the entrained gases in a helium headspace<sup>2</sup>. The gases were analysed by capillary gas chroma-

tography on a column which gives complete resolution of all the  $C_6$ – $C_7$  and part of the  $C_8$  hydrocarbons<sup>3</sup>. Individual hydrocarbons were identified from known retention times and by gas chromatography-mass spectrometry.

The samples analysed in the 4,000–13,000 feet depth interval are Upper Miocene in age whereas the samples extending down to 16,000 feet are Lower Miocene. There are a few silts and sands in the shallow part of the well, but most of the lithology is fine-grained gray shale with organic carbon contents in the range 0.75–1.3%. An over-pressured section extends from about 10,000 feet to total depth.

Figure 1 shows the distribution of total  $C_6$  and  $C_7$  saturated hydrocarbons, alkanes and cycloalkanes in ng per g of sediment. The generation curve for these hydrocarbons shows a threshold of intense generation around 10,000 feet and a peak around 13,500 feet. However, the distribution of individual hydrocarbons shows a different pattern. Figure 2 shows the distributions of two dimethylbutanes and two dimethylpentanes. The differences in these structures is that the 2,2-isomers contain a single quaternary carbon atom and no tertiary carbon atoms, whereas the 2,3-isomers contain two tertiary carbon atoms. The latter structure for both the substituted butane and pentane shows a strong increase in concentration around 10,000 feet. At this depth the subsurface temperature is ~115°C. In contrast, the structures with a quaternary carbon atom show slight increase at 12,000 feet with the major increase around 13,500 feet equal to a subsurface temperature of about 150°C.

Figure 3 shows the hydrocarbon distributions for a  $C_7$  branched alkane and a cycloalkane both containing a tertiary carbon atom. They are compared with a  $C_8$  branched alkane containing a quaternary carbon atom. Again, the latter compound shows no significant increase in concentration before reaching the 13,500-foot depth range. The compounds with the tertiary carbon atoms show this increase at 10,000 feet.

Figure 4 shows two dimethylcyclopentanes in which the only difference is the position of the methyl groups on the ring. In the 1,1-isomer there is a quaternary carbon atom whereas in the 1,2-isomer there are two tertiary carbon atoms. The latter shows increased concentrations at 9,500 feet, the former at ~11,500 feet.

The distribution patterns of the  $C_6$ – $C_8$  hydrocarbons in this well show that there is a significant difference in the time-temperature requirements for the formation of hydrocarbons of different structure. These differences occur over the depth interval from ~10,000 to ~13,500 feet. Deposition rates for the Miocene in this well were ~1,000 feet per Myr, indicating a time differential of ~3.5 Myr and, as previously indicated, a temperature difference of 35°C for the initiation of intense generation of these different hydrocarbons.

There are several possible causes of the observed distributions: (1) a change in organic source material with depth; (2) differential migration; and (3) a change in the generation mechanism as a function of increasing depth (temperature). A change of organic source material with depth can be ruled out by the similarity of capillary gas chromatography analyses carried out on pyrolysis products generated from the organic material<sup>4</sup>. Moreover, migration cannot be the explanation. Light hydrocarbons in this range diffuse from their point of origin towards the surface<sup>5</sup> in such a way as to cause a change in hydrocarbon concentration with molecular size because of differences in diffusion coefficients—for example, between *n*-propane and *n*-hexane. However, for structural isomers such as those in Fig. 2, the quaternary isomers diffuse more rapidly than the tertiary. Neopentane diffuses more rapidly than isopentane, for example<sup>6</sup>. Thus diffusion would lead to the opposite of the observed distributions and cannot be the cause. Similarly, other possible migration mechanisms do not explain the distributions. Separation of isomers due to partial adsorption during migration, or differences in boiling point, would both cause the quaternary structures to occur at shallower depths—to migrate ahead as on a laboratory chromatographic column. Bulk transport in the gas phase might result in some density separation, but again, the

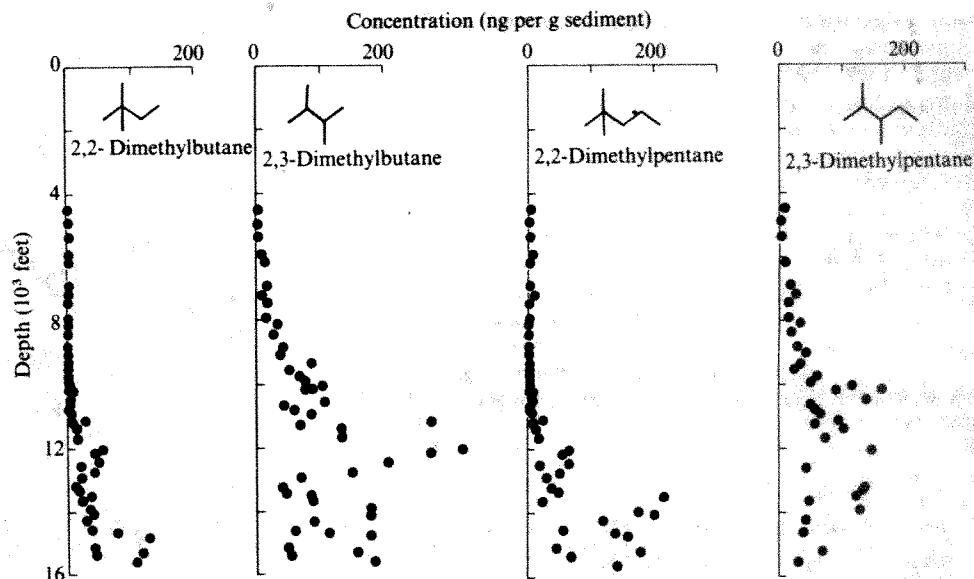

Fig. 1 Concentration plotted against depth of total  $C_6$  plus  $C_7$  saturated hydrocarbons in ng per g of dry sediment in the COST no. 1 well, Gulf of Mexico.

**Fig. 2** Concentration plotted against depth of two C<sub>6</sub> and two C<sub>7</sub> branched alkane isomers in the COST no. 1 well.

quaternary structures are the least dense and would be found shallower instead of deeper.

These arguments suggest that the generation mechanism itself must be the explanation for the profiles observed. It seems unreasonable at these low temperatures (<150 °C) to propose thermodynamic equilibrium between isomeric saturated hydrocarbons, so that we assume that the products preferentially formed at any particular depth result from whichever intermediate (carbonium ion or free-radical) forms most rapidly (kinetic control).

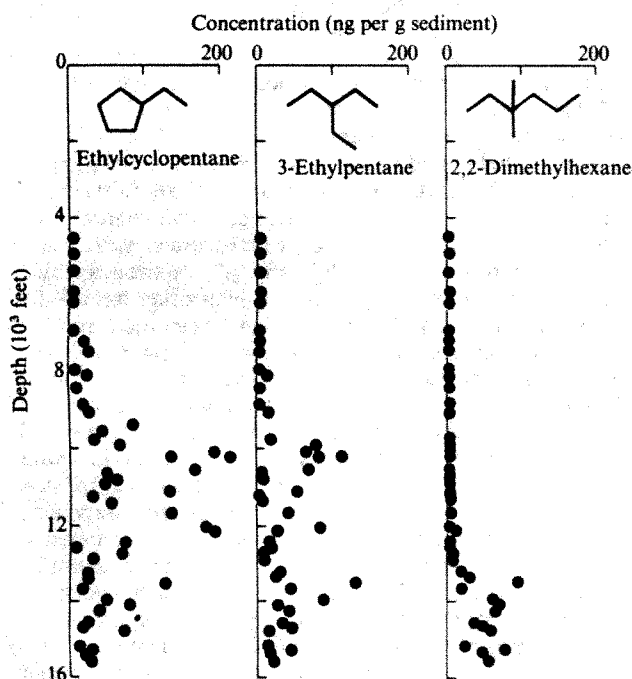

There are two major generation pathways to the observed products from kerogen. Carbonium-ion cracking dominates at lower temperatures (shallower depths) and free-radical cracking dominates at higher temperatures (ref. 1, pp. 122–130). Carbonium ions rearrange whereas free radicals do not<sup>7</sup>. Also, tertiary carbonium ions are more stable than the primary or secondary ions and the latter easily rearrange to the former<sup>7</sup>. Consequently, the increased yield of tertiary structures at 10,000 feet may be the result of intensified carbonium-ion

cracking and isomerization. Carbonium ions with quaternary structures would rapidly rearrange to tertiary products, so that no increase in quaternary hydrocarbons would be observed at this depth.

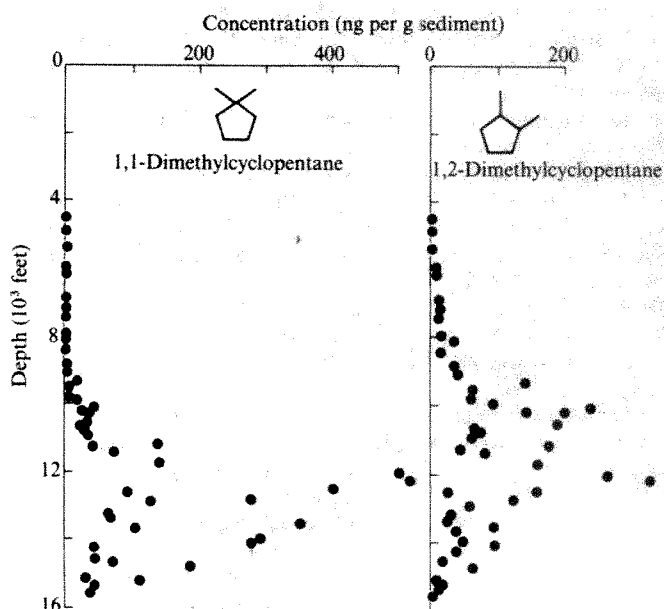

Eventually, as the sediments are buried deeper to higher temperatures, free-radical cracking takes over. This causes an increase in the yield of quaternary structures at 13,500 feet because these free radicals cannot rearrange.

The fact that the yield of tertiary structures is still high at that depth suggests either that tertiary free radicals also are cracking off or that some carbonium-ion cracking is still occurring.

Whether these structures are breaking off as free radicals in the configurations shown or are isomerization products of some carbonium-ion precursors, it is significant that the hydrocarbon content of these shale source-beds is varying substantially with depth. The composition of the C<sub>6</sub>–C<sub>8</sub> hydrocarbon mixture at 10,000 feet is quite different from that at 13,500 feet. This means that attempts to correlate crude oil composition with the hydrocarbons in a presumed source rock or to derive correlations between source rocks will need to account for the formation of different hydrocarbon structures in different time-temperature conditions.

**Fig. 3** Concentration plotted against depth of a C<sub>7</sub> cycloalkane and a C<sub>7</sub> and C<sub>8</sub> branched alkane in the COST no. 1 well.

**Fig. 4** Concentration plotted against depth of two dimethylcyclopentanes in the COST no. 1 well.

Individual hydrocarbons in the gasoline range ( $C_6$ – $C_8$ ) show a significant increase in concentration at varying depths in sedimentary rocks. Hydrocarbon structures with a tertiary carbon atom increased markedly at a subsurface depth equivalent to a time and temperature of 10 Myr and 115 °C. In contrast, structures with a quaternary carbon atom did not show a substantial increase until reaching a depth equivalent to 13.5 Myr and 150 °C. The difference in depth distribution is believed to be due to the formation of carbonium ions from the kerogen at lower temperatures than free radicals. The early-forming carbonium ions then rearrange to the stable tertiary structure. Greater energy (higher temperature) is required to crack the quaternary free-radical structures which do not rearrange.

## Holocene phosphorite on the East Australian continental margin

G. W. O'Brien & H. H. Veeh

The Flinders University of South Australia, Bedford Park, South Australia 5042, Australia

**Carbonate-fluorapatite, the major component of marine phosphorite, forms within organic-rich diatomaceous sediments in present day conditions along the continental margin of Peru-Chile and South-West Africa (Namibia)<sup>1–4</sup>. Both of these areas are 'West-Coast' phosphogenic provinces<sup>5,6</sup>, characterized by an eastern boundary current, with strong coastal upwelling and associated high organic productivity. We report here the first radiometric evidence supporting Holocene apatite formation in an 'East-Coast' phosphogenic province, the East Australian continental margin, an area of only moderate seasonal upwelling<sup>7,8</sup>.**

The phosphorites of the present study were recovered from the outer continental shelf and upper slope between 29 and 32° S (Fig. 1). In this region, the shelf is fairly narrow (25–40 km) and the slope is unusually steep, with the major shelf break occurring at depths<sup>9,10</sup> between 210 and 450 m. A prominent feature of the oceanography of this area is the East Australian Current, considered a complex series of anti-cyclonic eddies which move generally southwards along the coast<sup>11,12</sup>. Limited upwelling occurs off Evans Head and Laurieton<sup>7,8</sup> (31° 39' S), causing small but significant nutrient enrichments in surface waters.

Phosphorites on the East Australian continental margin were first described by von der Borch<sup>13</sup>, who suggested a mid-Miocene age for them on the basis of palaeontological evidence. Preliminary uranium-series disequilibrium studies<sup>14</sup> confirmed the relict nature of well consolidated, ferruginous phosphorite nodules from the Coffs Harbour region, but also indicated a much younger age ( $5.5 \times 10^4$  yr) for less well consolidated nodules from an area just south of Evans Head. We have examined phosphorites from different locations in an attempt to establish their distribution in space and time, and thus relate their formation to known environmental parameters in this area.

Fig. 1 Location map of phosphatic nodules on the East Australian continental margin. Bathymetric contours (in metres) redrawn from ref. 10.

The nodules fall into two easily distinguishable types—Types I and II. Type I nodules occur within a depth interval 360–420 m on the upper slope, predominantly in the Evans Head–Yamba Head area. These nodules lie within sediments rich in glauconite, biogenic carbonate and quartz and are fairly small (<4 cm diameter), earthy, friable and range in colour from near white to yellow-brown to dark grey. Microscopically, they are seen to be composed of an admixture of silt-sized angular quartz, green to green-brown rounded glauconite as well as calcareous skeletal material which has been cemented by light brownish-tinged cryptocrystalline apatite (collophane). Scanning electron microscopy (SEM, Fig. 2) shows that some phosphate is present as crystallites on the internal surfaces of foraminiferal tests, though no direct evidence for replacement of calcium carbonate by apatite has been observed in these nodules. X-ray diffraction analysis (XRD) of Type I nodules shows quartz, high and low-magnesium calcite, aragonite, glauconite and carbonate fluorapatite as major components. Location G16 differs in that the phosphorite there is present as a poorly consolidated material infilling the interstices between the septa of solitary corals. Type II nodules, which occur off Coffs Harbour in depths of <300 m, are typically fairly large (>5 cm), highly indurated, heavily ferruginized and usually have a 'glazed' appearance. XRD indicates quartz, glauconite, goethite and carbonate fluorapatite as major constituents. Calcite and aragonite are much less abundant in Type II nodules.

\* Determined by X-ray fluorescence spectrography.

† Average of 10 microprobe analyses; ‡ average of 14 microprobe analyses.

Table 1, which summarizes bulk analytical and average collophane microprobe analyses for several nodules, supports the above mentioned differences, with Type I nodules having much lower Fe<sub>2</sub>O<sub>3</sub> contents than do Type II. Whole rock P<sub>2</sub>O<sub>5</sub> contents are low, with a maximum of 15.3% in G7-10, which is slightly below the minimum 18% P<sub>2</sub>O<sub>5</sub> content (50% apatite) that is often taken to define a 'phosphorite'<sup>15</sup>. Strictly speaking, these are really phosphatic nodules.

Uranium-series age determinations were carried out on several Type I and Type II nodules and one solitary coral (Table 2) by methods previously discussed<sup>1-4, 16, 17</sup>. Briefly, the basic assumptions of the U-series method relevant to marine phosphorites are: (1) the uranium entered the apatite phase at the time of its formation, and the time of formation was short compared with the age to be measured; (2) the uranium was derived from seawater; (3) the apatite has remained a closed system with respect to the parent and daughter isotopes; and (4) the apatite was initially free of <sup>230</sup>Th. If these constraints are all satisfied, then the <sup>230</sup>Th/<sup>234</sup>U ratio provides a reliable estimate

of the time of apatite formation. Previous work<sup>4, 18</sup> basically validates assumptions (1)–(3), while the small amount of 'initial' <sup>230</sup>Th usually found in marine phosphorites can be corrected for<sup>4</sup>. The results show that all but one of the Type I nodules show finite ages, and three of these are Holocene. If a correction for non-radiogenic <sup>230</sup>Th is made, based on an assumed <sup>230</sup>Th/<sup>232</sup>Th ratio of 4.0 in common thorium<sup>4</sup>, the Holocene nodules would all be <5,000-yr old. Sample G16-3A represents the phosphatic infilling of a solitary coral. The solid base of the coral itself (100% aragonite) was also dated (G16-3B) and we believe this to be the first time that uranium-series dating of coexisting marine phosphorite and corals has been carried out. The results, which are consistent with the depositional sequence as observed under the microscope, coupled with the generally acknowledged reliability of uranium-series dating of corals, considerably strengthens the arguments presented here. Type II nodules are in radioactive equilibrium and thus beyond the limits of the dating method. Sample 1516-A has in fact suffered some leakage of <sup>234</sup>U similar to many nodules from other areas for which a Miocene age has been independently established<sup>17</sup>.

There are thus two distinctly different types of phosphorite occurring on the East Australian continental margin. Type II nodules, occurring in depths of <300 m, are relict and are probably of mid-Miocene age, as previously suggested<sup>13</sup>. The Type I nodules, on the other hand, are restricted to a narrow depth interval from 360 to 420 m and seem to have formed by cementation of upper-slope sediments with collophane. The spread of ages displayed by Type I nodules suggests that apatite formation has been a continuous process operating in this area for the last several hundred thousand years, rather than being restricted to high stands of sea level during the late Pleistocene<sup>4</sup>. In fact, one of the nodules (G7-12) has an age of 17,500 yr which is very close to the time of the maximum lowering of sea level associated with the last glaciation. The very young ages obtained for several of the samples indicate that apatite formation within East Australian upper slope sediments has only recently ceased, or is even continuing at present.

We have demonstrated that the East Australian continental margin is an area of Holocene phosphate deposition. The general geological and oceanographical characteristics of the region suggest that this deposit may be a modern analogue of McKelvey's<sup>5, 6</sup> East Coast phosphorite deposits. Previously, it has proved difficult to explain many East Coast phosphorite deposits in terms of intense coastal upwelling, and other models, such as an estuarine origin have been proposed<sup>19</sup>. However, a sizeable phosphate deposit, such as the East Australian continental margin deposit, can be produced, even in an area of only moderate seasonal upwelling. Perhaps the East Australian current, predominantly a shelf feature, has resulted in very low sedimentation rates on the upper slope, thus minimizing 'dilution' of the authigenically formed phosphate.

**Table 2** Uranium-series data for phosphatic nodules occurring on the East Australian continental margin

| Sample | Type  | Depth (m) | U (p.p.m.) | Th (p.p.m.) | <sup>234</sup> U/ <sup>238</sup> U | <sup>230</sup> Th/ <sup>234</sup> U | Age (×10 <sup>3</sup> yr) | Age* <sub>c</sub> | <sup>234</sup> U/ <sup>238</sup> U(IV) | U(IV)/U  |

Errors quoted based on counting statistics (±1σ).

\* Age corrected for common thorium using:  $^{230}\text{Th}_c = ^{230}\text{Th}_m - (4 \times ^{232}\text{Th} \exp(-\lambda_{230}t))$ , where  $^{230}\text{Th}_m$  = measured activity of  $^{230}\text{Th}$ .

**Fig. 2** *a*, Scanning electron micrograph of apatite crystallites on the internal surface of foraminiferal test contained in a phosphatic nodule. (Crystallites confirmed as phosphate-rich by energy dispersive X-ray analysis.) *b*, High magnification of *a* showing relationship of apatite crystals to foraminiferal calcite.

Samples from Locations G7, G16, and G18 were provided by Professor C. C. von der Borch and 1516 by J. Marshall. Others were collected during a CSIRO cruise of RV Sprightly in 1979. Microprobe analyses were performed at Broken Hill Proprietary, Melbourne Research Laboratories and X-ray fluorescence analyses were done by Dr A. R. Milnes. Financial support was provided by the Australian Research Grants Committee. *Note added in proof:* It has been pointed out to us by R. Foster, CSIRO Division of Soils, that the (apatite) crystallites (Fig. 2) could be mineralized bacteria because of the remarkable morphological similarity. If confirmed, this would imply that bacterial activity plays an important role in phosphorite genesis.

## Boninite at a continental margin

C. P. Wood

New Zealand Geological Survey, PO Box 30368, Lower Hutt, New Zealand

A lava interbedded with Cretaceous sediments deposited on the continental margin of New Zealand has phenocrystic chromite, olivine, low-Ca and high-Ca pyroxenes with quench morphology, normative quartz, and relatively high MgO, Cr and Ni, but very low Ti and Zr; it is shown here to conform to the term boninite as defined by Cameron *et al.*<sup>1</sup>. Such rocks are usually found in geologically oceanic situations, as in the Bonin, and Mariana arc-trench systems of the Western Pacific, or in ophiolites that represent uplifted, oceanic crust formed close to oceanic plate margins, particularly spreading centres, though not necessarily at mid-ocean ridges<sup>2-6</sup>. The New Zealand boninite closely resembles certain ophiolitic lavas, yet its association is not ophiolitic, and this part of New Zealand never was, nor ever became, an oceanic spreading centre<sup>7</sup>. Coeval basalts are alkalic, not tholeiitic as is usual and the occurrence warns against the use of basalt petrochemistry as an indicator of tectonic environment in the absence of supporting geological evidence.

Albian sediments of the Mangapokia Formation in eastern Wairarapa, in the North Island of New Zealand, accumulated as submarine fan or fan-delta deposits, probably at shelf depths in a fault-controlled basin<sup>8</sup>. They comprise at least 1,500 m of flysch-like sediments, with sporadic lavas and sills, most of which are spilitic, alkalic basalts, some with camptonitic affinities. However, near Nagahape almost 10 m of boninitic lava and

**Fig. 1** Textures of Kopi boninite. *a*, Acicular crystals and skeletal chains of augite, and a few lozenges of pigeonite jacketed by augite. Field width, 1.3 mm. *b*, Spinifex texture; oriented blades of chloritized pigeonite rimmed by augite, and a few, dark, cross-cutting olivine dendrites. Matrix is devitrified glass. Field width, 1.3 mm.

- 6 Average composition of fine-grained groundmass (nine positions; defocused beam) recalculated to 100%.
- 7 Average boninite analysis, standard deviations in parentheses; a, major elements in wt %, 1.92 (0.61) % H<sub>2</sub>O also present; b, trace elements in p.p.m.

hyaloclastite (known as Kōpi boninite) occur within a sequence of coarse quartzofeldspathic sediments derived from a continental hinterland. A water depth of 200–700 m at emplacement is suggested by the bulk sulphur content of 940 p.p.m., and average maximum vesicle diameter of 1.5–2 mm (refs 9, 10). Quartz, chlorite, calcite and laumontite in brecciated boninite indicate zeolite facies alteration, though dense rock is little affected.

Pillow lava with conspicuous, random needles of pyroxene predominates, though spinifex-textured rock is also present (Fig. 1). Magnesiochromite crystallized first, and is ubiquitous in trace amounts; with average ratios of Cr/(Cr+Al) = 0.71, and Mg/(Mg+Fe<sup>2+</sup>) = 0.51 it falls at the low-Cr, low-Mg margin of the compositional range of boninite and basaltic komatiite chromites<sup>1</sup>. Minor olivine (0.3–1.1 modal %) followed spinel, forming mainly subhedral crystals (<0.5 mm), but with some lantern-and-chain dendrites, particularly in the spinifex rock. Olivine has been replaced completely by quartz, calcite and iron oxides.

There are three types of phenocryst pyroxene, the earliest being rare, unzoned calcic bronzite in the range Mg/(Mg+Fe) = 0.86–0.89 (analysis 2, Table 1). Composite clinopyroxene crystals are the dominant phenocrysts (25.5–38.4 modal %), and in both habit and chemistry they closely resemble the pyroxenes in some rapidly cooled komatiites<sup>11</sup>. They form hollow needles up to 70 × 1 mm which show simple zoning, with a multiply twinned core of pigeonite rimmed by optically continuous augite. Core compositions are continuous with those of bronzite (Fig. 2), straddling the boundary between calcic clinobronzite (En<sub>85</sub>Fs<sub>11</sub>Wo<sub>4</sub>) and highly magnesian pigeonite (En<sub>76</sub>Fs<sub>14</sub>Wo<sub>10</sub>). The crystal forms suggest rapid crystallization from a supercooled liquid to produce these metastable clinopyroxenes, which plot in the miscibility gap between stable high-Ca and low-Ca pyroxenes.

Augite jackets the subcalcic clinopyroxene and sometimes mantles the hollow core; it also occurs as single-phase microphenocrysts and in skeletal chains. In the spinifex rock, oriented blades comprise augite rims on a chloritized core (Fig. 1). Compositions range from En<sub>55.9</sub>Fs<sub>13.4</sub>Wo<sub>30.7</sub> to En<sub>46.9</sub>Fs<sub>11.9</sub>Wo<sub>41.2</sub>, and as the skeletal and spinifex pyroxenes fall within the range of rim compositions (Fig. 2), it seems the composite crystals represent quench overgrowth of calcic clinopyroxene on an earlier, subcalcic core.

Groundmasses comprise fan-spherulitic integrowths mostly too fine to differentiate, but occasionally coarse enough to identify plagioclase (An<sub>67–79</sub>), clinopyroxene and magnetite

(TiO<sub>2</sub> ≈ 7.0%). Interstitial matrix in the spinifex rock varies from devitrified glass, through axiolitic spherulites to well developed, pin-wheel pyroxene spherulites. The average, bulk-matrix analysis (analysis 6, Table 1) resembles aluminous basaltic andesite. The whole-rock analysis (analysis 7a, Table 1) is less siliceous than boninite from the Bonin Islands, but resembles the basaltic lavas found in some ophiolite complexes such as Troodos<sup>2</sup>, and Betts Cove<sup>3</sup>. Cameron *et al.*<sup>1</sup> class all these as boninite, the name adopted here, but other terms such as basaltic komatiite<sup>3</sup>, low-Ti basalt<sup>4</sup>, and magnesian quartz tholeiite<sup>6</sup> have been used for the same rocks. Whatever the name, the combination of relatively high MgO, Cr and Ni, and extremely low TiO<sub>2</sub> and Zr in a quartz-normative

**Fig. 2** Compositions of pyroxenes in Kōpi boninite plotted in part of the system MgSiO<sub>3</sub>–FeSiO<sub>3</sub>–CaSiO<sub>3</sub>. ▲, Bronzite phenocrysts; ●, cores of composite phenocrysts; ■, rims of composite phenocrysts; □, skeletal and spinifex rim pyroxenes.

Fig. 3 Kopi boninite (■) and coeval alkaline basaltic rocks (●) plotted using immobile elements to discriminate between alkaline and tholeiitic fields (after ref. 14). a,  $\text{TiO}_2$  (wt%) against the ratio  $\text{Zr}/\text{P}_2\text{O}_5$  (p.p.m.). b, Zr (p.p.m.) against  $\text{P}_2\text{O}_5$  (%).

( $Q = 6.0\%$ ), basic composition places the lava clearly within a spectrum of basaltic to andesitic rocks that are otherwise known only from modern oceanic areas, or ancient ophiolites that were segments of oceanic lithosphere.

The early Cretaceous sediments of eastern Wairarapa are thought to overlie or to represent the youngest part of a sequence of several kilometres of marine sediment of continental provenance, deposited more or less continuously throughout the Mesozoic. An Albian tectonic event deformed the soft sediments and initiated open-shelf deposition<sup>8</sup> which continued till late Tertiary time, when the present uplift and deformation began. Minor intraformational slumping may have occurred during deposition of Mangapokia sediments, but there is no evidence to suggest allochthonous emplacement of the lavas. Thus there is no indication that the area was anything other than a faulted, continent margin at the time the lava was erupted.

In the discussion of genesis of low-Ti magmas, there is general agreement that multistage melting is necessary to give extreme depletion of incompatible elements<sup>1,4-6</sup>. Olivine tholeiite and derivatives, produced by voluminous first-stage melting, are the habitual associates of most low-Ti lavas. However, lavas coeval with the Kopi boninite are alkalic basalts and derivatives, with marked enrichment in P, Ti, Y, Zr and Nb (Fig. 3), presumably generated by deep, low-volume, first-stage melting of upper mantle. Eruption of one or more such magma batches would have efficiently depleted a portion of mantle which then could have risen as a small diapir to melt at shallower depths and produce boninite.

If such a process did occur it is perhaps unusual that the association of boninite with alkalic basalt is so rare. The closest comparison seems to be in the Othris Mountains of Greece, where Cameron *et al.*<sup>1</sup> reported boninite in the Agrilia Formation. There, the associated volcanics are mildly undersaturated, alkaline types<sup>12</sup> erupted at a continental margin during a period of slow splitting, possibly caused either by continental rifting, or the initiation of a marginal ocean basin and nearby subduction zone<sup>13</sup>. It is probable that the eastern margin of the early Cretaceous, New Zealand continent was deeply fractured enough to allow boninite magma to erupt, but even if continental splitting had started it clearly failed to develop. It is certain that a spreading centre never formed at the site of deposition,

and though there is a modern subduction zone to the east of northern New Zealand, the existence of one in early Cretaceous times is a moot point.

I thank P. R. Moore, I. G. Speden, and A. J. Tulloch for discussions and advice, and T. R. Grammer and N. Orr for technical help. Most analytical work was carried out in the Geology Department of Victoria University of Wellington.

## Coefficients of relatedness in sociobiology

Richard E. Michod

Department of Ecology and Evolutionary Biology, University of Arizona, Tucson, Arizona 85721

W. D. Hamilton

Museum of Zoology, University of Michigan, Ann Arbor, Michigan 48109

A much-discussed, quantitative criterion for the spread of an altruistic gene is Hamilton's rule<sup>1,2</sup>

$$\frac{c}{b} < R \quad (1)$$

where  $c$  and  $b$  are additive decrement and increment to fitness of altruist and recipient, respectively, and  $R$  is a measure of genetic relatedness between the two individuals. When rearranged as  $-c.1 + b.R > 0$ , the rule can be interpreted as requiring that the gene-caused action increase the 'inclusive fitness' of the actor. Since its introduction, Hamilton's rule and the attendant concept of inclusive fitness have gained increasing acceptance and use among biologists and have become integral in the field now named sociobiology. However, the essentially heuristic reasoning used in deriving these concepts, along with the lack of a complete specification even in the original outbred model<sup>2</sup>, have led to many investigations into the population genetical underpinnings of Hamilton's rule<sup>3-18</sup>. On the basis of these considerations, several reports<sup>3,10,12,13,18</sup> have proposed new formulae for  $R$ . These formulae have no obvious relation to each other or to the coefficients originally suggested by Hamilton. This proliferation of coefficients is undoubtedly confusing to many and the net effect may be to generate distrust both of the rule and of the notion of inclusive fitness. Our purpose here is to show that these various formulae for  $R$  (refs 3, 10, 12, 13, 18), although independently derived, are actually the same.

What is  $R$  in equation (1)? On the basis of a particular outbred model, Hamilton<sup>1,2</sup> claimed that Wright's<sup>19</sup> 'coefficient of relationship' was the required  $R$ . However, later, giving a heuristic development but no further model, Hamilton<sup>20,21</sup> modified his identification of  $R$  with Wright's coefficient by claiming that equation (1) requires, in principle, a regression coefficient of

genotype of recipient on genotype of altruist, whereas Wright's coefficient is the corresponding correlation coefficient. Such a correlation coefficient will often be the same as the regression coefficient but differs when the interactants are inbred to different extents<sup>18</sup>. These discussions<sup>1,2,20,21</sup> implied that  $R$  was independent of gene frequency and selection, and that equation (1) held for inbred populations (with the regression coefficient as  $R$ ).

However, in recent models<sup>3-17</sup>,  $R$  is taken to be the threshold value of  $c/b$ , below which the cost-benefit ratio must be for the gene to increase. The  $R$  formulated in this operational way need not necessarily correspond to any simple measure of genetic relationship. Some of these models<sup>3-11,14,15,17</sup> specify the whole mating process with respect to interactions within families. Other models<sup>12,13,16</sup> maintain the generality of Hamilton's<sup>2</sup> original approach, and apply to interactants of arbitrary relationship, but fail to specify the population and mating system processes which give rise to  $R$ . If Hamilton's rule is to be useful, it must turn out that  $R$ , as formulated by these various approaches, must not vary widely as gene frequency or the parameters of selection change, except as implied by the simple proportionality to  $c/b$ . In many cases of interest,  $R$  is constant<sup>4,7-9,15</sup>, but in others<sup>3,4,7,10-13,16</sup> dependencies on gene frequency and dominance enter into calculations of  $R$ .

Our analysis here will not consist of any derivations of the coefficients from the gene frequency dynamics, as that is done from different points of view in the various works to be considered<sup>3,10,12,13</sup>. Instead, we will simply convert these various coefficients into a common symbolism and show that they are, in fact, identical. However, before doing so, we should acknowledge an important aspect of the derivations: either selection

must be weak so that standard identity coefficients can be used as measures of genetic relationship, or rather special conditions must be imposed on the models so that there is no selection at internal points of the pedigree patterns studied.

The genetic relationship between two diploid individuals,  $X$  and  $Y$ , at a single locus can be summarized by the following nine 'condensed' identity coefficients  $\Delta_1, \Delta_2, \dots, \Delta_9$ , where  $\Delta_i$  is the probability of genetic identity event  $i$  obtaining (Fig. 1 upper left-hand corner)<sup>22</sup>. These coefficients consider identity states among all four alleles present in  $X$  and  $Y$ . The traditional two-allele coefficients, interpreted as probabilities, are

$$f_X = \Delta_1 + \Delta_2 + \Delta_3 + \Delta_4 \quad f_Y = \Delta_1 + \Delta_2 + \Delta_5 + \Delta_6 \quad (2a)$$

$$f_{XY} = \Delta_1 + \frac{1}{2}(\Delta_3 + \Delta_5 + \Delta_7) + \frac{1}{4}\Delta_8 \quad (2b)$$

where  $f_X$  and  $f_Y$  are the inbreeding coefficients of  $X$  and  $Y$ , respectively, and  $f_{XY}$  is the 'coefficient of consanguinity' between  $X$  and  $Y$ , or the probability that a random allele from  $X$  is identical by descent with a random allele from  $Y$  at the locus of interest. Letting  $X$  denote the altruist and  $Y$  the recipient, the coefficient which we will use to relate the others may now be defined as

$$R = \frac{f_{XY}\alpha + (\Delta_1 + \frac{1}{2}\Delta_3)(1-\alpha)}{\frac{1}{2}\alpha + f_X(1-\frac{1}{2}\alpha)} \quad (3)$$

where  $\alpha = 2q + 2h - 4qh$ ,  $p$  is the frequency of the non-altruist allele  $A$  with  $q = (1-p)$  the frequency of the altruistic allele  $a$ , and  $h$  is the probability that a heterozygote performs an altruistic act. If we express the phenotypes as the probabilities of behaving altruistically (0,  $h$ , 1 corresponding to  $AA$ ,  $Aa$ ,  $aa$ ),

**Fig. 1** Joint and marginal distribution of genetic identity states with genotypes. The nine 'condensed' identity states are given in the upper left-hand corner with probabilities  $\Delta_i$  ( $i = 1, 2, \dots, 9$ ),  $\sum_i \Delta_i = 1$ . The alleles of  $X$  are on top and the alleles of  $Y$  on the bottom. A line connecting alleles indicates identity by descent. Given the occurrence of each identity state, the distribution of the genotypes of  $X$  and  $Y$  are given within the large side and top three boxes, respectively. For example, if identity state 5 obtains, then  $X$  is  $AA$ ,  $Aa$ ,  $aa$  with probabilities  $p^2$ ,  $2pq$ ,  $q^2$ , respectively; the like probabilities for  $Y$  are  $p$ ,  $0$ ,  $q$ , respectively. Given the distribution of identity states, the marginal distribution of genotypes is given in the top left corner of each of these six large boxes. The joint distribution of genotypes are given in the nine large boxes towards the bottom right of the figure. For example, if identity state 3 obtains, then

$$\begin{aligned} P_{00} &= p^2, & P_{01} &= pq, \\ P_{03} &= P_{10} = P_{11} = P_{12} = P_{20} = 0, \\ P_{21} &= pq & \text{and} & P_{22} = q^2. \end{aligned}$$

| $\frac{1}{2}$ | $h$   |       | $P_{10}$                | $P_{11}$                | $P_{12}$                |
| 1             | 1     |       | $P_{20}$                | $P_{21}$                | $P_{22}$                |
|               |       |       | $P_{Y0} = p^2 + f_Y pq$ | $P_{Y1} = 2pq(1 - f_Y)$ | $P_{Y2} = q^2 + f_Y pq$ |
|               |       |       |                         |                         | 1                       |

$P_{ij}$  is the joint distribution of genotypes  $i$  and  $j$  and  $P_{X_i}$ ,  $P_{Y_i}$  are the marginal distributions of the genotypes of  $X$  and  $Y$ , respectively ( $i, j = 0, 1, 2$ ). From the table, the following expressions can be calculated for use in calculations concerning equations (5):  $E(X_i) = hP_{X1} + P_{X2}$ ,  $E(Y_i) = hP_{Y1} + P_{Y2}$ ,  $E(Y_j) = \frac{1}{2}P_{Y1} + P_{Y2} = q$ ,  $E(X_j) = \frac{1}{2}P_{X1} + P_{X2} = q$ ,  $E(Y_i X_j) = \frac{1}{2}hP_{11} + hP_{12} + \frac{1}{2}P_{21} + P_{22}$ ,  $E(X_i X_j) = \frac{1}{2}hP_{X1} + P_{X2}$ ,  $E(X_i Y_j) = \frac{1}{2}hP_{11} + \frac{1}{2}P_{12} + \frac{1}{2}P_{21} + P_{22}$ ,  $E(X_j^2) = \frac{1}{2}P_{X1} + P_{X2}$ .

and the genotypes as the fractions of altruistic alleles (0,  $\frac{1}{2}$ , 1 corresponding to AA, Aa, aa), then  $\alpha$  is simply the regression of phenotype on genotype in a randomly mating population. This convention regarding the genotypes and phenotypes will be used throughout. With a change in notation,  $R$  as given by equation (3) is identical to the coefficient derived by Fleiss and Holtzman<sup>13</sup> (equation (10), where  $P(H) = \Delta_1 + \frac{1}{2}\Delta_3$  and their  $h = \frac{1}{2}\alpha$ ). It is important to note that if the gene effects are additive, if there is no inbreeding or if  $p = q = 0.5$ , then equation (3) reduces to the coefficient proposed by Hamilton<sup>20,21</sup>:

$$R = \frac{2f_{XY}}{1 + f_X} \quad (4)$$

Consequently, the regression coefficient (equation (4)) will be a good estimate of  $R$  in many cases of interest. We now show that the coefficients derived elsewhere in the literature<sup>3,10,12,18</sup> are identical to equation (3).

Below, we index genotypes with a single subscript  $i$ , with  $i = 0, 1, 2$  corresponding to genotypes AA, Aa, aa, respectively. Let  $P_{ij}$  be the joint distribution of genotypes  $i$  and  $j$  in the population with  $i$  being the genotype of  $X$  and  $j$  the genotype of  $Y$  (Fig. 1, Table 1). Let  $X_i$ ,  $X_j$  and  $Y_i$ ,  $Y_j$  denote the genotype and phenotype of  $X$  and  $Y$ , respectively.

Orlove<sup>3</sup> and Orlove and Wood<sup>10</sup> derive  $R = \text{Cov}(X_i, Y_j) / \text{Cov}(X_i, X_j)$  in an outbred model of kin selection in haplodiploid families. Their coefficient<sup>3,10</sup> equals

$$R = \frac{\text{Cov}(Y_i, X_j)}{\text{Cov}(X_i, X_j)} \quad (5)$$

if there is no inbreeding. However, as we now show, equation (5) is more generally correct, as well as being the most concise and intuitive representation of equations (3) or (17).

To relate equation (5) to equation (3), we must first calculate the required covariances. The information needed to do so is given in Table 1, in which the genotypes and phenotypes of  $X$  and  $Y$  are given along with the joint and marginal probabilities. Using this information to evaluate the covariances in equation (5), we obtain directly

$$\frac{\text{Cov}(Y_i, X_j)}{\text{Cov}(X_i, X_j)} = \frac{\frac{1}{2}P_{11}h + hP_{12} + \frac{1}{2}P_{21} + P_{22} - (\frac{1}{2}P_{Y1} + P_{Y2})(hP_{X1} + P_{X2})}{\frac{1}{2}hP_{X1} + P_{X2} - (hP_{X1} + P_{X2})(\frac{1}{2}P_{X1} + P_{X2})} \quad (6)$$

From Table 1, we can also obtain for future use

$$\text{Cov}(Y_i, X_j) = \frac{1}{2}P_{11} + \frac{1}{2}P_{12} + \frac{1}{2}P_{21} + P_{22} - (\frac{1}{2}P_{X1} + P_{X2})(\frac{1}{2}P_{Y1} + P_{Y2}) \quad (7)$$

$$\text{Var}(Y_i) = \frac{1}{4}qp(1 + f_Y) \quad (8a)$$

and

$$\text{Var}(X_i) = \frac{1}{4}qp(1 + f_X) \quad (8b)$$

Substituting equation (7) into the numerator of equation (6)

$$\text{Cov}(Y_i, X_j) = \text{Cov}(Y_i, X_j) + (h - \frac{1}{2})(\frac{1}{2}P_{11} + P_{12} - qP_{X1}) \quad (9)$$

The denominator of equation (6) can be simplified directly to

$$\text{Cov}(X_i, X_j) = pq[\frac{1}{2}\alpha + f_X(1 - \frac{1}{2}\alpha)] \quad (10)$$

As shown in Fig. 1 (see also refs 12, 22, 23), it is possible to express the joint probabilities of the interactions,  $P_{ij}$ , in terms of the condensed identity coefficients and the gene frequency. In particular,

$$\begin{aligned} P_{11} &= 2pq(\Delta_7 + \frac{1}{2}\Delta_8 + 2pq\Delta_9) \\ P_{12} &= pq(\Delta_5 + 2q\Delta_6 + q\Delta_8 + 2q^2\Delta_9) \end{aligned} \quad (11)$$

These formulae (equation (11) and Fig. 1) are only strictly correct for neutral genes; however, it is hoped that they are approximately correct if selection is weak. Substituting equation (11) into equation (9) and recalling

$$P_{X1} = (1 - f_X)2pq$$

we obtain after some algebra

$$\text{Cov}(Y_i, X_j) = \text{Cov}(Y_i, X_j) + \frac{1}{2}pq(\alpha - 1)[\Delta_5 + \Delta_7 + \frac{1}{2}\Delta_8] \quad (12)$$

Letting  $r_{XY}$  be the correlation between the genotypes of  $X$  and  $Y$ , we have

$$\text{Cov}(Y_i, X_j) = r_{XY}[\text{Var}(X_i) \text{Var}(Y_i)]^{1/2} \quad (13)$$

However<sup>19</sup>,

$$r_{XY} = \frac{2f_{XY}}{[(1 + f_X)(1 + f_Y)]^{1/2}} \quad (14)$$

On substituting equations (8) and (14) into equation (13), we obtain

$$\text{Cov}(Y_i, X_j) = f_{XY}pq$$

and so equation (12) becomes

$$\text{Cov}(Y_i, X_j) = f_{XY}pq + \frac{1}{2}pq(\alpha - 1)(\Delta_5 + \Delta_7 + \frac{1}{2}\Delta_8) \quad (15)$$

After rearranging equation (15) and using equation (2b)

$$\text{Cov}(Y_i, X_j) = pq[f_{XY}\alpha + (1 - \alpha)(\Delta_1 + \frac{1}{2}\Delta_3)] \quad (16)$$

On substituting equations (16) and (10) into equation (5), we obtain equation (3) as was to be shown.

Michod<sup>12</sup> (equation (3)) derived the following coefficient for use in Hamilton's rule

$$R = \frac{2xpp' + (1 - x)(1 - 2q)\rho'}{1 + x - 2q} \quad (17)$$

$$\rho' = \frac{(\Delta_1 + \frac{1}{2}\Delta_3)}{q + pf_X} + \frac{q(\Delta_5 + \Delta_7 + \frac{1}{2}\Delta_8)}{q + pf_X} \quad (18a)$$

and

$$\rho' = \frac{\Delta_5 + \Delta_7 + \frac{1}{2}\Delta_8}{1 - f_X} \quad (18b)$$

which are Jacquard's conditional genic structures<sup>12,22,23</sup>. These conditional coefficients in equation (18) give the probability with which  $X$  can predict, on the basis of pedigree ties, the allelic distribution in gametes of  $Y$ . This probability depends on

whether  $X$  is homozygous (equation (18a)) or heterozygous (equation (18b)). In addition, the variable  $x$  appearing in equation (17) is the frequency of altruistic homozygotes among the total class of altruists and is

$$x = \frac{q^2(1-f_x) + f_x q}{q^2(1-f_x) + q f_x + (1-f_x)2pqh} \quad (19)$$

Equation (19) corrects a mistake in Table 1 of Michod<sup>12</sup> where it was thought that the average inbreeding coefficient (averaged over the frequencies of  $X$  and  $Y$  in the population) should be used in equation (19). This is incorrect due to the conditional nature of the altruism. As the gene is only expressed in  $X$ , when  $X$  is in a certain relationship to  $Y$  (the relationship being summarized by the  $\Delta$  values), it is only the frequency of homozygous altruists among all  $X$  individuals which matter in equation (19). This fact alone accounts for the incorrect impression, given in Fig. 2b of that paper<sup>12</sup>, that dominant genes could never increase in frequency. (Fig. 2a of ref. 12 is unaffected by these considerations.) After substituting equations (19) and (18) into equation (17) and collecting the  $\Delta$  values in terms of  $f_{XY}$ , equation (3) is obtained after some rearrangement.

In conclusion, the various coefficients derived in the literature<sup>3,10,12,13,18</sup> for use as  $R$  in Hamilton's rule are equivalent. These coefficients were originally derived from very different points of view. Given the results here, these various approaches support each other and suggest that the one pleomorphic coefficient [equations (3), (5) or (17)] is, indeed, correct.

## Proline and valine—cues which stimulate grasshopper herbivory during drought stress?

Brent M. Haglund

Montana Department of Natural Resources and Conservation,  
Biology Department, Montana State University, Bozeman,  
Montana 59717

**Insect herbivores, including members of Orthoptera and Lepidoptera, benefit from increased nitrogen in their food, particularly if it is in the form of easily digested amino acids<sup>1,2</sup>. I report here experimental evidence that grasshoppers detect and preferentially feed on grasses treated with the amino acids proline and valine, which commonly increase in plants under drought stress<sup>3</sup>. This ability may lead to insect concentrations on drought-stressed and nitrogen-enriched plants and thus exacerbate acridid population outbreaks through enhanced growth and survival.**

Ecological studies of grasshoppers and locusts have often considered weather factors to be important determinants of population size or growth rate<sup>4-9</sup>. Dry soil conditions in particular seem to favour population increases of many economically important Orthopteran species<sup>10</sup>. It has been hypothesized that grasshopper growth rates, and consequent survival, increase sharply in drier conditions when perennial grasses have elevated nitrogen (N) levels in parts above ground<sup>1</sup>. Insect herbivores are generally likely to benefit from increased dietary N (ref. 2).

Such elevated nitrogen levels may be the result of increased concentrations of proline<sup>3</sup>. A highly soluble amino acid, proline does not hamper the activities of many photosynthetic enzymes and is able to provide osmotic adjustment in conditions of drought stress or salt accumulation<sup>11-17</sup>. Glycine and valine may function similarly<sup>18</sup>. Leaf laminae accumulate the largest quantities of the newly synthesized proline although it is also found in most other above-ground parts<sup>19</sup>. Genetic varieties of plants which accumulate larger concentrations of free proline tend to survive water stress better and grow faster after stress is relieved<sup>20</sup>.

Mobile herbivores which can detect and concentrate their feeding on N-enriched plants will be favoured relative to conspecifics lacking these abilities. These abilities will be particularly important in environments with food patches of varying N quality. For example, in the northern Great Plains of North America, soil moisture is usually limiting to plant growth in summer. Here forage quality—normally influenced by rainfall—is patchy because thundershowers are local and infrequent.

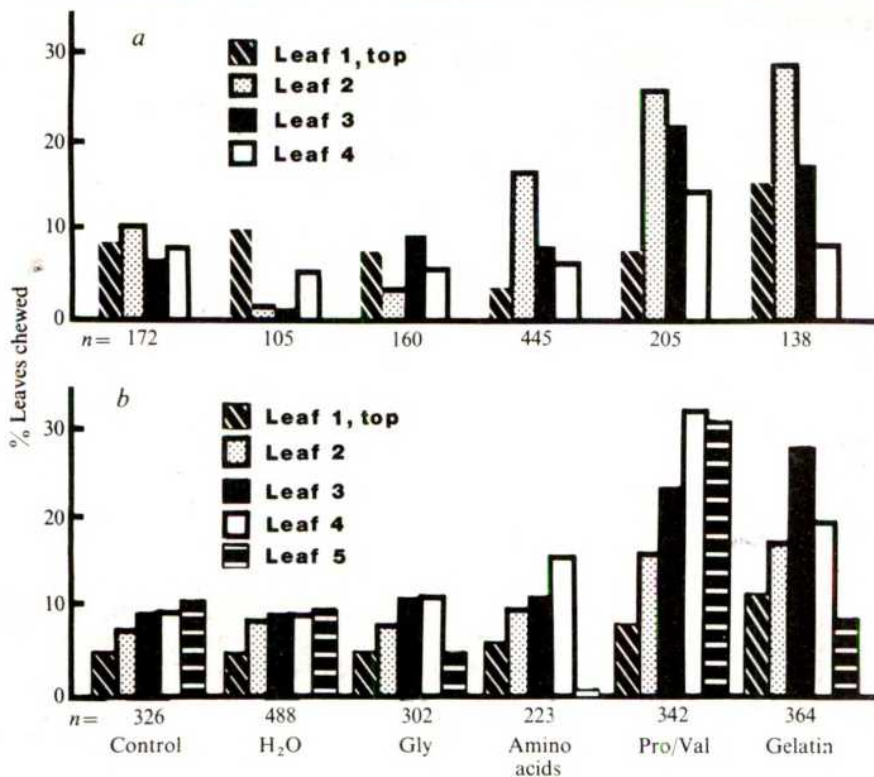

I conducted a field experiment in a native Montana grassland to test the hypothesis that chewing insects can detect plants with elevated amino acid nitrogen levels within the range of levels that occur naturally. A completely randomized two-factor design was replicated three times. Plots of 2 m<sup>2</sup> separated by 4 m buffers were treated. Treatment levels by factor were Factor A (irrigation): none and 25 mm soil surface irrigation; Factor B (foliar sprays): none, 1.6 litre distilled H<sub>2</sub>O, Pro + Val in equal amounts, mixed amino acids in equal amounts (Ala, Arg, Gly, His, Lys, Met, Phe), Gly and gelatin. For the last four treatment levels, amino acids or protein were dissolved in 1.6 litre distilled H<sub>2</sub>O with a concentration equal to 0.7534 g N (except Gly which equalled 7.534 g N). The treatment level was chosen to lie within the range of plant water stress responses and raise the estimated N standing crop by 10%, based on 84 g m<sup>-2</sup> standing crop plant biomass at an estimated 2% total N.

The irrigation treatments were carried out on 9 July 1979 between 0700 and 1000 h; foliar spraying was done by hand on 10 July 1979 from 1230 to 1700 h. Except for the Gly treatment, which was 10 times more concentrated, the maximum possible individual amino acid concentration was 0.93% of plant dry matter compared with measured proline levels of 1% or greater for barley<sup>14</sup>, Bermuda grass<sup>15</sup>, tobacco<sup>16</sup>, clover<sup>21</sup> and several halophyte species<sup>11,17</sup> under water stress. Proline can accumulate to as much as 10-20% of shoot dry weight in *Triglochin maritima*<sup>17</sup>. I estimated that less than one quarter of the spray from any of the treatments contacted the leaves due to low plant density at the site.

The dependent variable measured was percentage of leaves chewed on stems of *Agropyron smithii* with four intact leaves, a C<sub>3</sub> grass, and *Bouteloua gracilis* with five intact leaves, a C<sub>4</sub> grass, stratified by leaf position enumerated from youngest to oldest. Virtually complete collections of stems of these two species were gathered by hand on 6 September 1979. The total number of stems sampled for each of the foliar spray treatments is shown in Fig. 1. Only chewed leaves were counted—broken leaf tips were not recorded.

Chewing was affected by two amino acid treatments but was unaffected by irrigation or the remaining amino acid sprays ( $\chi^2$  test,  $P < 0.001$ ). Because irrigation treatments showed no influence on chewing ( $P > 0.3$ ) data were pooled across water levels in the subsequent analysis. Paired *t*-test analysis of percentage of leaves chewed by leaf position indicated

**Fig. 1** Percentage of leaves chewed by grasshoppers in response to amino acid foliar spray treatments on two grass species: *Agropyron smithii* (a) and *Bouteloua gracilis* (b). Each bar represents the percentage of leaves at each position that were chewed. Leaf position is assigned from the top to the bottom of the stem. Sample size ( $n$ ) is the total number of stems assayed within each treatment.

significant differences ( $P < 0.01$ ) on the second and third leaves of *A. smithii* and on the third, fourth and fifth leaves of *B. gracilis* with Pro and Val. With the gelatin treatment, only the second leaf of *A. smithii* and the third and fourth leaves of *B. gracilis* showed greater numbers of chews. At the time of spraying the first leaf of both species had not emerged; the fourth leaf of *A. smithii* was already brown and probably dead.

Grasshoppers were not responding to an improvement in plant condition due to N enrichment. Forty randomly selected plants from each foliar treatment were measured for stem length, leaf length (numbers two and three) and colour (completely brown or some green remaining). With analysis of variance no difference in these variables could be detected among the treatments ( $P > 0.2$ ).

I conclude that grasshoppers (over 95% of the chewing insects on the plots in July and August and dominated by *Opeia obsura*, *Trachyrachis kiowa* and *Melanoplus sanguinipes*) can detect either proline or valine on plant tissue. They selected grass treated with proline and valine and also grass treated with gelatin containing proline (15%) and valine (3%) residues. Although glycine is an important component (45%) of gelatin, glycine alone had no effect on insect chewing. The possibility that grasshoppers are capable of chemodetection is supported by the documentation<sup>22</sup> of the presence of amino acid receptors in other chewing insects, the Lepidoptera. Aphids are also known to detect amino acids<sup>23</sup>. Furthermore, proline is reported to be a feeding attractant to the snail *Biomphalaria glabrata*<sup>24</sup>.

Proline is used by animals in various ways including intermediate energy metabolism, enzyme synthesis and, in large amounts, for connective tissue. It can also be used for osmoregulation. Insects able to find and consume proline in above average quantities are likely to grow faster. I suggest that proline accumulations will affect chewing insects much less in wet years or in conditions of augmented soil moisture through weather modification or irrigation.

Management implications of this plant-herbivore interaction include the possibility of lowered insect herbivory to the extent that weather modification or irrigation could relieve plant

drought stress. Plants intimately coevolved with their insect herbivores may find partial relief from drought stress by herbivory because it reduces leaf area, allowing water to become more concentrated in remaining leaf tissue<sup>25,26</sup>. However, crop plants genetically engineered for greater proline production in the hopes of raising their drought tolerance and thereby increasing their yield may be at increased risk to insect pests<sup>27</sup>.

I thank T. W. Weaver III for ideas. This research was funded by the High Plains Cooperative Program, Montana Department of National Resources and Conservation grant no. 14-06-D-7577, Water and Power Resources Service, US Department of Interior. Land was made available by the Livestock and Range Research Station, Agricultural Research Service, US Department of Agriculture.

## Insect populations respond to fluctuating environments

David A. Jillson

Department of Zoology, University of Vermont, Burlington, Vermont 05405

Models of populations inhabiting regularly fluctuating environments suggest that the nature of the population fluctuation is determined by the relative sizes of the characteristic response time of the population,  $T_R$ , and the period of the environmental variation. For example, May's<sup>1</sup> model of a density-regulated population inhabiting a sinusoidally varying environment showed that when the characteristic response time was long relative to the period of environmental fluctuation,  $Y$ , the population averaged out environmental fluctuations, whereas for  $T_R$  short relative to  $Y$ , the population tended to track environmental variations. Characteristic response time is a measure of how quickly a system returns to equilibrium following a disturbance, and for the logistic model and its immediate relatives,  $T_R$  equals the inverse of population growth rate,  $r$ . The present study investigated the responses of populations of the flour beetle, *Tribolium castaneum*, cultured in a series of regularly fluctuating environments. Responses to environmental fluctuations were striking at all periods of environmental fluctuations, but population density declined as environmental period lengthened.

Environmental fluctuations were created by altering the amount of culture medium (95% unbleached wheat flour, 5% brewer's yeast by weight) between 32 and 8 g at regular intervals. This experimental regime represents fluctuations in carrying capacity, for *Tribolium* population size is known to be positively correlated with the amount of culture medium<sup>2</sup>. *T. castaneum* populations were cultured in each of five experimental regimes—a constant 20-g environment, and fluctuating environments with 4-, 8-, 12- and 16-week periods. The periods were chosen to represent intervals ranging from the equivalent of, to much longer than an estimate of *T. castaneum* characteristic response time. *Tribolium* characteristic response time was calculated by taking the inverse of population growth rate. This procedure is accurate if the logistic model is an adequate representation of *Tribolium* population dynamics and was used as simple approximation to  $T_R$ . Estimates of *T. castaneum* population growth rates derived from age-specific survivorship and fecundity schedules range from 0.7 to 1.3 per week<sup>3-6</sup>, corresponding to  $T_R$  of approximately 1 week. Estimates of  $r$  taken from exponential growth phases of *T. castaneum* population growth data<sup>6-8</sup> yield longer response times of 2-6 weeks, and may be more indicative of attainable rates of growth.

Thirty cultures of the corn oil-sensitive strain of *T. castaneum*<sup>9-16</sup> were initiated with 30 adults in a 1:1 sex ratio and 75 unsexed small larvae. Populations were censused at 2-week intervals: larvae, pupae and adults were counted and returned to fresh medium of the appropriate amount. All populations were cultured in 20-g medium for the initial 18 weeks of the experiment to allow the populations to approach demographic and numerical equilibrium. At week 18, six populations were randomly assigned to each of the five treatments, and the series of environmental fluctuations began, continuing until week 64.

Regular though small fluctuations were characteristic of the mean population size over time in the constant 20-g environment (Fig. 1). These intrinsic fluctuations were partly caused by cannibalistic interactions<sup>15-18</sup>. A significant linear regression of mean population size with time showed that populations increased modestly at a rate of only four animals per week.

In contrast, populations in the 4-week treatment increased in density substantially. During weeks 18 to 54, populations increased on average by 21 animals per week. Fluctuations were also seen in this treatment—local increases in population size occurred during periods of 32-g medium, and, except for the decline from week 54 to 56, every decrease occurred in 8-g medium. Bursts of recruitment occurred in the relatively abundant 32-g medium, enhancing the number of small larvae successfully recruited. After two weeks of 8-g medium, 32 g were

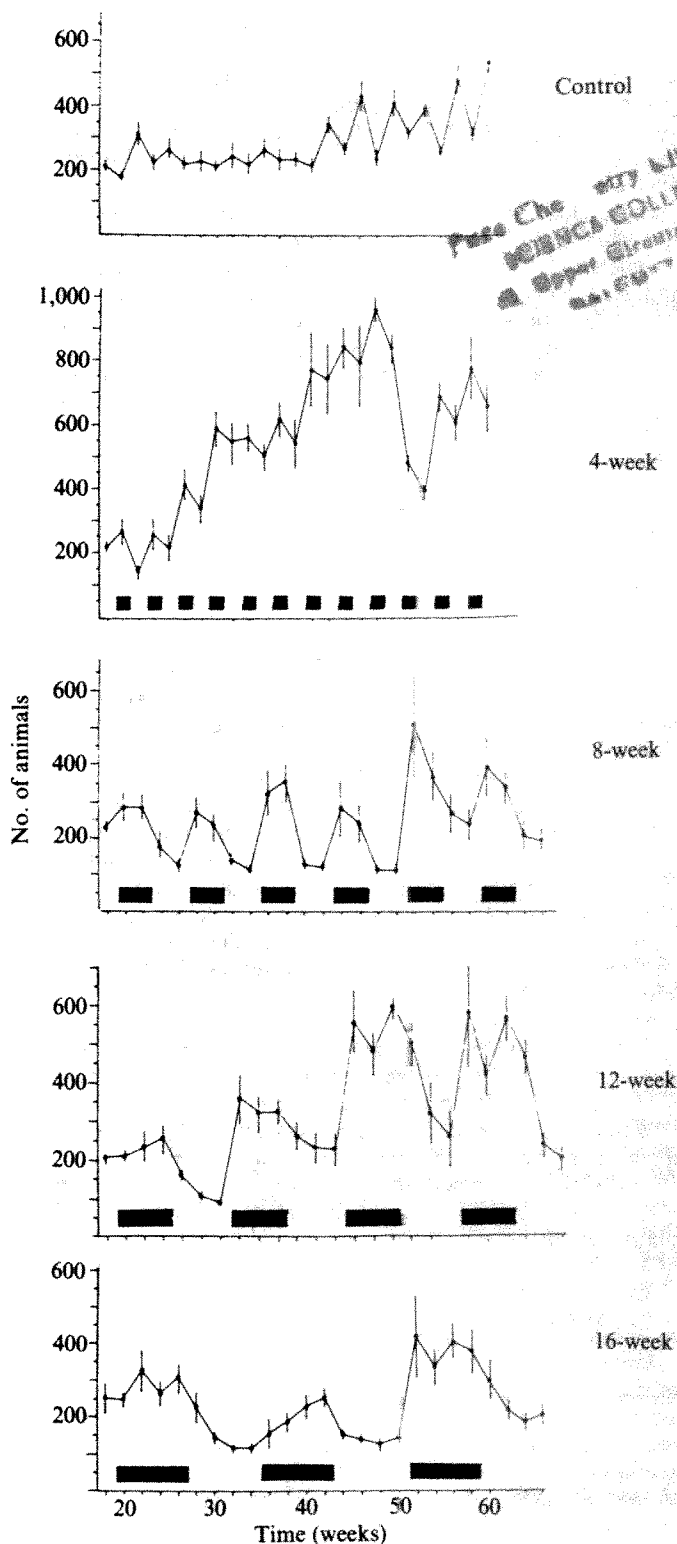

Fig. 1 Mean number ( $\pm$ s.e.) of animals in constant and fluctuating environments. Shaded bars in fluctuating treatments represent periods of 32-g medium, intervening periods had 8-g medium.

available again, the small larval cohort had become large larvae and were able to pupate in abundant medium where cannibalism was reduced. It is most interesting that the 4-week period of environmental fluctuation was ideally suited to the 4-week *T. castaneum* developmental period by maximizing the recruitment of small larvae and minimizing cannibalism on the vulnerable pupae. This treatment attained the highest population densities of the experiment, approximately twice that of the other treatments. This does not agree with predictions that fluctuations in carrying capacity reduce the long-term average population number below that attained in a constant environment<sup>1,19,20</sup>. Wool and Sverdlov<sup>21</sup> reported a similar discrepancy—*Tribolium* productivity tended to be higher in temporally variable than in constant environments. Predictions of a reduction in mean population size were premised on the logistic model, which fails to incorporate the effects of cannibalism, an important factor in *Tribolium* population dynamics<sup>17,18</sup>.

Populations inhabiting the 8-week treatment responded to environmental fluctuations differently from those in the 4-week cycle. Periods of abundant resources supported high densities and vice versa. In contrast to the 4-week treatment, these populations increased only moderately with time. Although bursts of recruitment occurred in 32-g conditions, each cohort of small larvae suffered high losses due to cannibalism when pupation occurred in crowded 8-g conditions.

In the 12-week treatment, mean population size again responded to environmental fluctuations, with population abundance directly proportional to the amount of culture medium. Population peaks tended to contain local dips, reflecting intrinsic patterns of cannibalism on eggs by a cohort of large larvae. Populations in the 16-week treatment also clearly mimicked the physical regime. The three complete cycles of culture medium resulted in three population cycles. Populations in the 12- and 16-week treatments were able to recruit young and undergo pupation in a sequence of 32-g medium, but the next cycle of recruitment was delayed by 6 and 8 weeks respectively by the intervening 8-g period, effectively reducing mean population size.

The proportion of adults in the control and 4-week cycle was relatively constant, and did not display any strong correlation with environmental variability. In contrast, the age distribution in the 8-, 12- and 16-week treatments followed environmental fluctuations, with 80–90% adults found during periods of sparse culture medium, alternating with 20–30% adults in periods of 32-g medium. These demographic oscillations were predominantly caused by recruitment of substantial numbers of immatures in 32-g medium whereas adult numbers remained relatively constant over time.

*Tribolium* populations clearly exhibited changes in density and age distribution in concert with temporal changes in resource availability. In addition, the large mean population size attained in the 4-week treatment was caused by a particular temporal pattern of environmental variation which suited this animal ideally. Although the mean amount of culture medium with time was the same in all treatments, 20 g, differing sequences of resource distribution yielded large differences in population size.

## Multiple extraocular photoreceptive areas on genitalia of butterfly *Papilio xuthus*

Kentaro Arikawa, Eisuke Eguchi\*, Akihiro Yoshida & Kiyoshi Aoki

Life Science Institute, Sophia University, 7-1 Kioicho, Chiyoda-ku, Tokyo, Japan

Extraocular photoreception has been reported in several orders of insects, and direct photoreception by the central nervous system (CNS) has been shown to be related to the circadian clock in many cases<sup>1</sup>. For example, CNS photoreceptors have been found in the brain and the last abdominal ganglion of the cockroach, *Periplaneta americana*, and in the brain of the silkworm, *Hyalophora cecropia*<sup>2</sup>. In other cases dermal light sensitivity has been deduced from behavioural responses. For instance, the larvae of *Tenebrio molitor* avoid light even after decapitation<sup>3</sup>. The antennae of *Aphis fabae* seem to be the site of light sensitivity responsible for the animal's photokinetic activity<sup>4</sup>. Dermal light sensitivity is demonstrable in all the tergites of the larvae of *Acilius japonicus* and *Dytiscus marginalis*, particularly well developed in the region of terminal abdominal spiracles<sup>5</sup>. We report here, however, the electrophysiological response and morphological characteristics of presumptive photoreceptive sites on the genitalia of the Chinese yellow swallowtail butterfly, *Papilio xuthus* L.

Electrophysiological recordings were made on summer forms of *P. xuthus* collected from a wild population in June 1980. For anatomical studies we used spring forms reared on a semi-artificial diet in the laboratory at 20 °C and with a 8L:16D light regime.

We found that two (N5, N6) of the six pairs (N1–N6, numbered from the most anterior pair) of nerve roots belonging to the last abdominal ganglion contained afferent photosensitive axons. Recordings could be made easily from cut proximal ends of these nerves by means of suction electrodes (Fig. 1a): responses consisted of sustained trains of spikes.

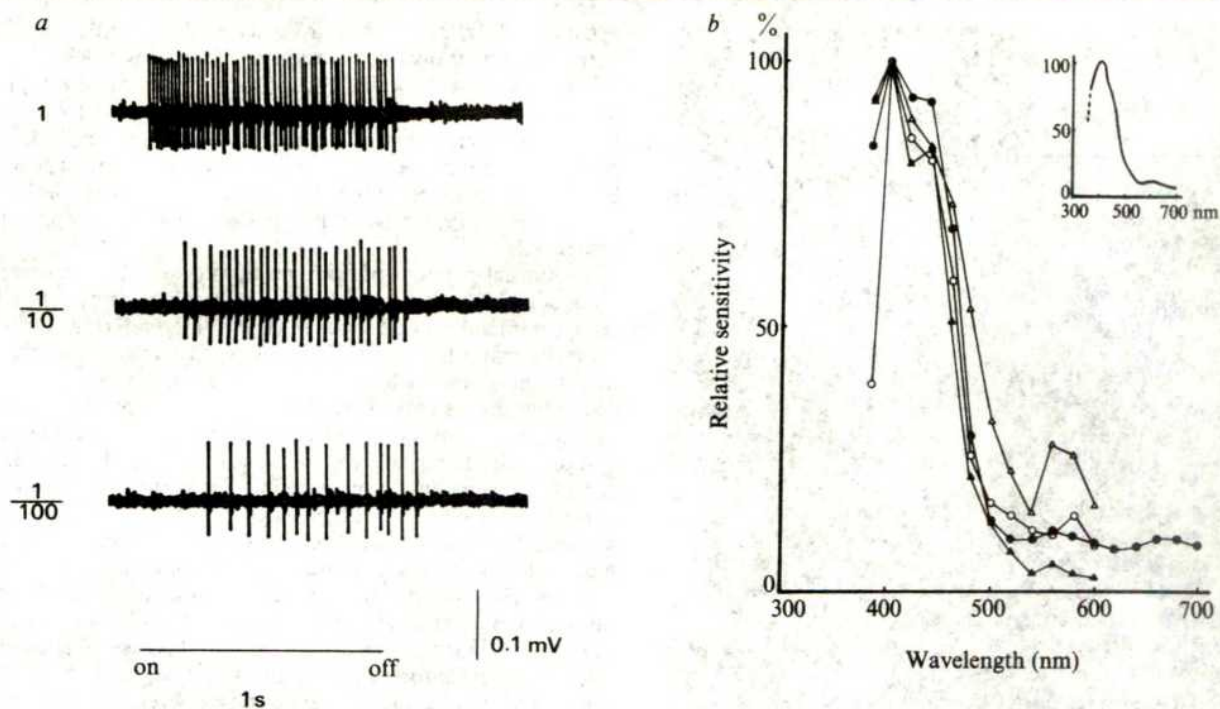

In white light, impulse frequency is related to log *I* (light intensity) by an S-shaped curve. The latent period varies inversely with *I* (Fig. 1a). Spectral sensitivity was determined for the photosensitive units by using 17 monochromatic light bands of 380–700 nm; it peaked at about 400 nm (Fig. 1b). Only one class of units has been recognized.

However, exploration with a 1-mm spot of light demonstrated two distinct photoreceptive areas on each side of the genital region, one (P1) sending afferents to root N6, and the other (P2) connecting with the CNS through N5. P1 and P2 are located in different areas specific to males and females. By anatomical isolation (for P1) and cutting of other nerves (for P2) the photoreceptor sites can be localized as follows.

In males ♂ P1 lies in the scaphium whereas ♂ P2 is on the fultura inferior (Fig. 2a). The scaphium is a sclerotized plate-like structure on the dorsal surface of the tuba analis, and the fultura inferior is a ventral part of the terminal diaphragm of

**Fig. 3** Presumed photoreceptive cell in the male scaphium. *a*, Overall view (scale = 1  $\mu$ m); *b*, detail of lamellated structure in the cytoplasm of the cell (scale = 0.1  $\mu$ m). Specimens were prefixed for 4–5 h with 2.0% glutaraldehyde and 2.0% paraformaldehyde in 0.1 M cacodylate buffer solution at pH 7.4 at room temperature. After washing, the tissue was post-fixed for 2–3 h in 2.0%  $\text{OsO}_4$  in the same buffer, dehydrated in an acetone series and embedded in Epon. Cut with a diamond knife, sections were stained with uranyl acetate and lead citrate and observed with a JEM 100B electron microscope. N, nucleus; B, basement membrane; L, lamellated body; E, epidermal cell; O, oil droplet.

male butterflies. In females  $\text{P1}$  lies on the papilla analis and  $\text{P2}$  lies laterally on the membrane between the papilla analis and the lamella postvaginalis (Fig. 2*b*). The papillae anales covered with chitinous hairs are strongly sclerotized lobes between which the anus and ostium oviductus open to the exterior.

Externally these various photoreceptor sites are marked by small areas of transparent cuticle, which elsewhere is pigmented and opaque. Thus the scaphium is pale brown over most of its surface but has a transparent area on its inner margin. Also the papilla analis is strongly pigmented except for a concave posterior region which is transparent and free of hairs (Fig. 2*d*).

When the transparent  $\text{P1}$  genital areas are covered with opaque material the afferent responses in  $\text{N6}$  are blocked completely. When this opaque material is removed, light-induced spikes reappear as in the normal preparation (Fig. 1). This shows that the photoreceptive elements of  $\text{P1}$  are illuminated through its local clear cuticular area. Similar transparent spots as described above, characterize the  $\text{P2}$  area but the effect of screening them has not been tested yet.

To localize further the receptor elements involved in  $\text{P1}$  and  $\text{P2}$  we examined these areas by transmission electron microscopy. That revealed, directly under the basement membrane of the epidermis, cells containing well-developed lamellated

organelles (Fig. 3*a*). These are essentially the same under the corresponding transparent cuticle of both  $\text{P1}$  and  $\text{P2}$ .

These lamellated bodies occupy a large volume of cytoplasm and may be associated with the photosensitivity. Lamellated bodies resembling those identified in the butterfly scaphium and papilla analis have been observed in the eyes of other invertebrates—for example, in the distal photoreceptor cells of the eye of the scallop *Pecten*<sup>6</sup> and the proximal region of cephalopod visual cells<sup>7</sup>.

The visual pigment of both vertebrates and invertebrates is embedded in elaborate disk-like or microvillus arrays of photoreceptor membrane. However, the epidermal cells of these butterfly photoreceptors show no such surface cytoplasmic membrane system, suggesting that they are not the light sensitive units in this case. However, there are other cells directly beneath the transparent cuticle and epidermis, with extensive cytoplasmic membrane systems, and they may be the photoreceptive organelles. A more convincing demonstration of such a function would depend on both proof of the appropriate axonal or synaptic connection to supply the observed spikes in  $\text{N6}$ , and a more detailed study of the lamellated membrane systems. Fine structural changes due to light and dark adaptation, as well as evidence for localization of visual pigment molecules might also prove diagnostic in this case. Whether and how these receptors are functional in copulation or other reproductive behaviour remain to be discovered.

We also obtained responses to white light stimulation of the genitalia with 6 other species of Papilionidae and 10 species from 6 of the 7 other butterfly families found in Japan (Libytheidae have not been tested yet). However, no such responses could be detected electrophysiologically in either nocturnal (two species tested) or diurnal (four species tested) moths.

## Reversible activation–inactivation of renin in human plasma

Brenda J. Leckie & Norah K. McGhee

Medical Research Council Blood Pressure Unit, Western Infirmary, Glasgow G11 6NT, UK

Renin, an aspartate protease, cleaves the  $\alpha$ -globulin angiotensinogen to produce the decapeptide angiotensin I, which is then converted to the vasoactive hormone angiotensin II by the action of a peptidase 'converting enzyme'. An inactive form of renin<sup>1–3</sup> sometimes termed prorenin<sup>4</sup> is present in normal human plasma. Its enzymatic activity is increased by exposure to a pH of 3.0 or 3.3 followed by dialysis towards neutral pH. Only a small proportion of the inactive renin is activated during the acid stage of dialysis, most of the activation apparently taking place during the subsequent dialysis to pH 5.7 (ref. 4) or 7.5 (ref. 5). Furthermore, if inhibitors of serine proteases are added to the plasma, the amount of inactive renin activated by this

dialysis procedure is reduced<sup>4,6</sup>. These results suggest that acid-activation is mediated by serine proteases. The role of enzymes such as plasma kallikrein, plasmin and renal kallikrein as physiological activators of inactive renin has recently been discussed<sup>5,9</sup>. In our study of the activation of plasma inactive renin we have now found that, contrary to previous reports<sup>4,5</sup>, complete activation of inactive renin takes place during the acid stage of dialysis. This activation can be reversed if plasma is rapidly adjusted to pH 7.4 and warmed. The next step in the acid-activation procedure, that is, dialysis to neutral pH, renders the initial acid-activation irreversible. These results were completely unexpected, and we offer an explanation that reassesses the nature of inactive renin and the activation process.

In the first series of experiments we studied the change in the renin concentration of normal male plasma during acid-activation in the presence and absence of soya bean trypsin inhibitor (Fig. 1). Samples of plasma (0.5 ml) were dialysed to pH 3.0 for 24 h at 4°C (ref. 1) and then taken to pH 7.4 at 4°C. At intervals, plasma was removed from the dialysis bags and transferred to 50 µl soya bean trypsin inhibitor (SBTI) solution<sup>6</sup> to

**Fig. 1** The renin concentration (ordinate) in normal human plasma during dialysis at 4°C to pH 3.0 followed by dialysis to pH 7.4. *a*, 0.5-ml samples of plasma were dialysed against 15 ml of pH 3.0 glycine/HCl buffer<sup>1</sup> at 4°C. At 0, 10 and 24 h, samples were removed from the dialysis bags and added to 50 µl of a 5 mg ml<sup>-1</sup> solution of SBTI to give a final concentration of 19 µmol per 1 SBTI. 50 µl of 3 M Tris-HCl buffer was added and the renin concentration assayed immediately by measuring the rate of angiotensin I generation from ox angiotensinogen<sup>10</sup>. ●, Immediate assay; ○, assay after 1 h at 37°C; ▲, assay after 5 h at 37°C. *b*, As for *a* except that 19 µmol per 1 SBTI was added to the plasma before the start of dialysis. Mean  $\pm$  s.e.m. of four experiments.

**Fig. 2** ●, Plasma was dialysed to pH 3.0 for 24 h at 4°C then 1/10 volume of 3 M Tris-HCl buffer added and the plasma warmed at 37°C. After 4 h the remaining plasma was dialysed to pH 3.0 and dialysed back to pH 7.4 at 4°C. Controls were dialysed to pH 7.4 for 48 h at 4°C (□). ▲, Plasma was dialysed to pH 3.0 for 24 h at 4°C and dialysed back to pH 7.4 at 4°C before the addition of 3 M Tris-HCl buffer and warming. ○, Plasma was trypsin-activated before being treated as described above. Mean  $\pm$  s.e.m. of three experiments.

give a final concentration of 19 µmol l<sup>-1</sup> SBTI. The inhibitor was used to prevent any activation of inactive renin by plasma proteases after removal of the sample from the dialysis bag<sup>6</sup>. The pH of the plasma was adjusted to between 7.4 and 7.5 at 4°C with the addition of 50 µl 3 M Tris-HCl buffer, pH 7.6, and the samples were immediately assayed for renin<sup>10</sup>. The renin was re-assayed after the samples had been incubated for 1 h at 37°C and again after 5 h. In a parallel series of experiments, 19 µmol l<sup>-1</sup> SBTI was added to the plasma before the start of the dialysis. Samples were dialysed as before, except that no further SBTI was added before adjustment of the pH and the samples were assayed for renin. Figure 1*a* shows the results of experiments in which plasma was dialysed without SBTI and assayed for renin immediately after adjustment to pH 7.4. During dialysis at pH 3.0 the renin concentration increased from 41  $\pm$  4 µU ml<sup>-1</sup> to 95  $\pm$  8 µU ml<sup>-1</sup> (mean  $\pm$  s.e.m.,  $P < 0.01$ ). During the subsequent dialysis to pH 7.4, the renin concentration did not change: 98  $\pm$  9 µU ml<sup>-1</sup> at 24 h (that is, 48 h from the start of the experiment) and 89  $\pm$  6 µU ml<sup>-1</sup> after 40 h (64 h from the start). Thus dialysis to pH 3.0 completely activated the inactive renin in this plasma. We confirmed that activation was complete by treating a separate portion of the plasma with trypsin<sup>10</sup>, which gave a renin concentration of 100  $\pm$  12 µU ml<sup>-1</sup> similar to that of 95  $\pm$  8 µU ml<sup>-1</sup> obtained with acid alone.

A different pattern was obtained if the samples were allowed to stand at 37°C for 1 h before being assayed. In this case, the renin concentration apparently increased to only 52  $\pm$  6 µU ml<sup>-1</sup> after the pH 3.0 stage of dialysis, but to 91  $\pm$  7 µU ml<sup>-1</sup> after dialysis to pH 7.4. If the plasma was assayed after 5 h at 37°C there was an apparent lack of activation during the pH 3.0 stage of dialysis. This pattern of activation is similar to that obtained elsewhere<sup>4,5</sup>.

Figure 1*b* shows the results of the experiments in which SBTI was added to the plasma before the start of dialysis. The activation obtained during the pH 3.0 stage of dialysis was similar to that for renin in plasma dialysed without SBTI. However, during the dialysis to pH 7.4 in the presence of SBTI the renin concentration in the plasma fell slowly over 40 h so that the final value of 58  $\pm$  5 µU ml<sup>-1</sup> was lower than that after the dialysis to pH 3.0 alone ( $P < 0.05$ ) and also lower than the

renin concentration in plasma dialysed at pH 3.0 and then taken to pH 7.4 for 40 h in the absence of SBTI ( $P < 0.01$ ). When samples that had been dialysed in the presence of SBTI were warmed at 37 °C and re-assayed, no apparent activation of renin was noted throughout both periods of dialysis.

These results showed that the activation of inactive renin induced by acid dialysis could be reversed if the plasma was rapidly neutralized and warmed. We investigated the reversal in a second series of experiments using another sample of pooled normal plasma. The plasma was dialysed to pH 3.0 for 24 h at 4 °C, assayed for renin then adjusted to pH 7.4 with 3 M Tris-HCl buffer at 4 °C and re-assayed. The plasma was warmed at 37 °C and the renin concentration measured at intervals. After 4 h at 37 °C the remaining plasma was again dialysed to pH 3.0 for 24 h and dialysed back to pH 7.4 for a further 24 h at 4 °C to determine whether the renin could be re-activated. A control dialysis to pH 7.4 for 48 h at 4 °C was carried out, and the effect of activation by trypsin was also tested. Figure 2 shows that exposure to pH 3.0 increased plasma renin concentration from  $19 \pm 3$  to  $82 \pm 2 \mu\text{U ml}^{-1}$ . During the incubation at 37 °C the renin concentration fell to the level in untreated plasma. If this incubated plasma was either acid-activated or trypsin-activated the renin concentration was restored to  $81 \pm 4 \mu\text{U ml}^{-1}$ , or  $97 \pm 11 \mu\text{U ml}^{-1}$  respectively. Therefore, the loss of renin on warming at 37 °C is not an irreversible denaturation similar to that of active renin exposed to pH 11.4 for 2 h (ref. 11). Incubated plasma dialysed to pH 7.4 showed a renin concentration of only  $36 \pm 6 \mu\text{U ml}^{-1}$ . This was higher than the renin levels in untreated plasma but it is possible that cryoactivation<sup>4</sup> had occurred during the 48 h at 4 °C.

Experiments were also carried out with plasma that had been dialysed to pH 3.0 and dialysed back to pH 7.4 for 48 h at 4 °C

before addition of 3 M Tris-HCl buffer and incubation at 37 °C. This plasma showed no reversal of the high renin concentration when warmed, nor did trypsin-treated plasma (Fig. 2).

The reversible activation-inactivation of renin in plasma was not due to an assay artefact. Falsely high renin concentrations can be obtained if proteolytic enzymes present in the radioimmunoassay mixture destroy the iodinated angiotensin I (results in preparation). False high results could also be obtained if a substance that cross-reacted with our angiotensin I antibody was generated during the dialysis of plasma to pH 3.0. A falsely low result could be obtained if the angiotensin I produced during the renin assay was destroyed by peptidases. However, none of the plasma samples contained detectable amounts of angiotensin I-like material before the start of the incubation with ox angiotensinogen. Thus the high renin concentrations obtained after dialysis of the plasma to pH 3.0 were not due to high 'blank' concentrations of angiotensin I (Fig. 3). The rate of production of angiotensin I was proportional to the time of incubation with ox angiotensinogen (Fig. 3), for all samples of treated plasma, except three out of six samples that had been dialysed to pH 3.0 without subsequent dialysis to pH 7.4. In these, the rate of angiotensin I generation decreased with increasing time of incubation in the renin assay. This cannot be due to an artefact such as substrate exhaustion which should equally affect other samples of the same renin concentration, but might be expected if the 'activated' renin in acid-treated plasma was being inactivated during the renin assay. We measured the recovery of angiotensin I incubated with plasma in the presence of angiotensin I antibody<sup>10</sup>. Recovery was >96% during the period of the renin assay, after correction for any generation of angiotensin I in the plasma. Therefore the antibody could protect angiotensin I against peptidases in the treated plasma samples. We considered the possibility of artefacts due to the presence of a protease such as cathepsin D which could generate angiotensin I from ox angiotensinogen. However, cathepsin D is not likely to cleave ox angiotensinogen at our assay pH of 6.9–7.0 (ref. 12). We conclude therefore that our results reflect a genuine change in the enzymatic activity of plasma inactive renin.

Since this study we have heard that another group using a different renin assay method also finds that plasma inactive renin is activated by exposure to acid alone (W. Hsueh, personal communication). Hsueh *et al.*<sup>13</sup> suggest that acidification alters the structure of the inactive renin molecule in such a way as to render it more susceptible to the action of proteases such as renal kallikrein<sup>9</sup>. We suggest an alternative explanation. Human plasma contains many protease inhibitors. There are high molecular weight forms of renin in mouse plasma that may consist of active renin bound to a plasma protein<sup>14</sup>. Furthermore, inactive forms of renin in extracts of pig<sup>15</sup>, rabbit<sup>16</sup> and dog<sup>17</sup> kidney consist of active renin bound to a renin 'inhibitor'. The inactive renin in human plasma may be a similar material. Exposure to acid may result in a conformational change in either renin or inhibitor leading to dissociation of the complex. Restoration of alkaline pH and incubation at 37 °C could result in re-association. By contrast, dialysis of the acidified plasma towards pH 7.4 at 4 °C could result in loss of the binding capacity of the inhibitor if plasma serine proteases either destroy the inhibitor by proteolysis or bind to it in competition with renin.

**Fig. 3** Rate of production of angiotensin I from ox angiotensinogen by renin in two samples of normal plasma, using an antibody-trapping method<sup>10</sup>. Plasma was treated as follows: ●, dialysed to pH 3.0 at 4 °C and dialysed back to pH 7.4 at 4 °C; ○, dialysed to pH 3.0 at 4 °C, rapidly adjusted to pH 7.4 at 4 °C and assayed; □, as for ○ but the plasma was incubated for 5 h at 37 °C before assay; ×, untreated plasma; Δ, trypsin-activated plasma (sample b only). The pg angiotensin I per 90 µl incubation mixture (ordinate) is plotted against time of incubation (abscissa). The range of the radioimmunoassay is 30–500 pg angiotensin I per 90 µl. Note that all samples of plasma including (○) and (□) show undetectable amounts of angiotensin at the start of the assay and that rate of production of angiotensin I is linear with time except for plasma b treated as for (○) (see text). In plasma a, heating at 37 °C for 5 h reduced the renin concentration below that of untreated plasma although for four separate experiments this was not significant ( $P > 0.05$ ). Bars show s.e. for triplicate assays.

## Ability of kallikrein to generate angiotensin II-like pressor substance and a proposed 'kinin-tensin enzyme system'

Kikuo Arakawa & Haruo Maruta

Department of Internal Medicine, Fukuoka University School of Medicine, Fukuoka, Japan 814

Pig pancreatic kallikrein liberates kallidin from kininogen<sup>1</sup>, whereas trypsin releases bradykinin<sup>2</sup>. Recently, both kallikrein and trypsin have been reported to convert inactive plasma renin to active renin<sup>3,4</sup>. However, we found that at pH 6.0, trypsin generated an angiotensin II-like pressor substance from human plasma protein in the absence of converting enzyme<sup>5</sup>. This has been isolated and found to have the same amino acid composition as angiotensin II<sup>6</sup>. Thus, *in vitro* trypsin can directly liberate both the depressor, bradykinin, in weak alkaline conditions, and the pressor, angiotensin II, at weakly acidic pH, from the appropriate substrates. We have now investigated whether kallikrein—a serine protease like trypsin—also generates a pressor substance at weakly acidic pH. Our results demonstrate that it does. We therefore suggest that kallikrein may be involved in a direct link between the pressor and depressor systems and we propose the term 'kinin-tensin system' for this sort of one-enzyme system capable of generating both depressor and pressor substances.

Human plasma protein Cohn's fraction IV-4 was used as substrate because it is rich in angiotensinogen<sup>7</sup>, as well as kallidinogen<sup>8</sup>. However, it was not a pure preparation, and was shown to contain renin which can be inactivated by alkali treatment<sup>9</sup>. Possible contamination with prorenin, cathepsin D and angiotensin I-converting enzyme was excluded or eliminated as follows: first, to activate any prorenin present, fraction IV-4 was treated by acid according to Yokosawa *et al.*<sup>3</sup>, and second, inactivation of the activated renin was achieved by treatment with alkali according to Arakawa *et al.*<sup>9</sup>. Trypsin- or kallikrein-activatable prorenin<sup>3,4</sup> was similarly treated. As shown in Table 1, the absence of angiotensin I formation indicated that these treatments were effective in removing any activatable prorenin and renin. Acid protease, or cathepsin D activity was not detected using denatured bovine haemoglobin as the substrate<sup>10</sup>. Angiotensin I-converting enzyme activity was also not detected when assayed by the method of Cushman and Cheung<sup>11</sup>. Thus, the alkali-treated substrate was shown to be free from any interfering components.

For pure pig pancreatic kallikrein two components, kallikrein A and B, were revealed by cellulose acetate electrophoresis at pH 8.6 (150 V, 1.5 h). Trypsin and chymotrypsin migrate different and could not be detected. The preparation did not hydrolyse benzoyl-L-tyrosine ethyl ester<sup>12</sup>, which indicated that there was no contamination by chymotrypsin, and it was also shown to be free from cathepsin D and angiotensin I-converting enzyme, by the same methods used for the above substrate.

The pretreated human plasma protein fraction IV-4 and the pure kallikrein preparation were incubated at pH 3.0–10.0, and after incubation vasoactive substances (Table 2) were analysed using the rat blood pressure bioassay. The bioassay showed formation of a pressor substance at pH 4.0–6.0, and depressor

| 60  | 0                           | 0          | 0.03   | 8.9                         | 0          | 15.7        |
| 120   | 0                           | 0          | 0.03   | 8.0                         | 0          | 14.0        |

Before incubation, to activate acid-activatable prorenin which might be contained in fraction IV-4, it was treated by dialysis against 0.05 M glycine-HCl buffer containing 0.1 M NaCl, pH 3.3, for 20 h, followed by a second dialysis against 0.1 M Tris-HCl buffer containing 0.1 M NaCl, pH 7.5, for 2 h. To inactivate the resultant activated renin, it was treated at pH 11.3 with 1.0 M NaOH for 2 h. pH was adjusted to 7.0 with 1.0 M HCl and it was dialysed against distilled water, and lyophilised. All these experiments were done at 4 °C. To activate trypsin- or kallikrein-activatable prorenin, 10 mg of the above-treated fraction IV-4 of 920 ng angiotensin I equivalent were dissolved in 1 ml of 0.1 M Tris-HCl buffer, pH 7.5, and added with 0.4 mg of trypsin (Miles, specific activity 3,000 NF units) or 0.5 mg of hog pancreatic kallikrein (Sanwa Chemicals, specific activity 768 µg equivalents bradykinin per min per mg, pH 8.0). Incubation was at 25 °C for 10 min in the case of trypsin and 1 h for kallikrein. The reaction was stopped by the addition of 5 mg aprotinin (Bayer, 5,000 KIU per mg protein). Finally, 100 µl of the above trypsin- or kallikrein-treated mixture were incubated with 10 mg of the renin-free substrate, or alkali-treated fraction IV-4<sup>3</sup>. The incubation was done in 2 ml of 0.1 M sodium phosphate buffer, pH 6.0, containing 200 µl of 0.1 M Na<sub>2</sub>EDTA, 20 µl of 0.45 M 8-hydroxyquinoline sulphate and 5 µl of 10% 2,3-dimercapto-1-propanol as angiotensinase inhibitors, at 37 °C for 0, 15, 30, 60 and 120 min. Reaction was stopped by boiling for 10 min. Products were bioassayed in rat blood pressure, and radioimmunoassayed for angiotensin I (AI-RI) and angiotensin II (AII-RI). Control experiments using 10 mg of acid- and alkali-treated fraction IV-4 without treatment by trypsin or kallikrein showed no formation of pressor substance. Trypsin- or kallikrein-treated fraction IV-4 produced a small amount of angiotensin II, but not angiotensin I.

substance(s) at the other pHs. Pepstatin, a renin inhibitor<sup>13</sup>, did not inhibit the pressor formation (Table 2), indicating that a renin-like enzyme was not involved. In control experiments without kallikrein, the alkali-treated fraction IV-4 did not generate any pressor substance in identical conditions, as reported elsewhere<sup>5,9</sup>. Kallikrein alone without substrate also did not generate pressor. These data are therefore consistent with the liberation of a vasoconstrictor by kallikrein and parallel previous results with trypsin<sup>5,6</sup>.

The pressor effect was not only similar in pattern to that of angiotensin II, but was also inhibited by the angiotensin II-antagonist, [1-Sar,8-Ile]-angiotensin II (Fig. 1), but not by SQ 14225, the converting-enzyme inhibitor (Fig. 2). Bioassay value of the pressor activity coincided with the radioimmunoassay value for angiotensin II, but not for angiotensin I, as shown in Table 2. It therefore seems likely that the pressor effect is due to the release of angiotensin II, in contrast to angiotensin I formed from the non-alkali-treated substrate in the absence of kallikrein<sup>9</sup>. Unless unknown mechanisms are involved, it is probably derived from angiotensinogen by a single cleavage. The methods used in the purification of the kallikrein and substrate indicate that the activation of prorenin<sup>3,4</sup> is not involved. Involvement of tonin is also unlikely because tonin has never been found in any animal organ other than rat submaxillary gland and pure pig pancreatic kallikrein is unlikely to contain it.

Thus both trypsin and kallikrein have been shown to be involved in the direct release of both pressor and depressor

**Table 2** Comparison of values of the pressor substance formed at pH values 3–10 by kallikrein assayed by different methods

| pH | Total amount of pressor substance formed after 18 h incubation |            |             |                             |            |             |

| 7  | 5.5  | 13         | 15.7        | 0                           | 0          | 14.8        |
| 8  | 75.0   | 0          | 15.4        | 0                           | 0          | 4.9         |
| 9  | 54.0   | 0          | 6.6         | 0                           | 0          | 2.7         |
| 10 | 69.0   | 0          | 7.1         | 0                           | 0          | 3.0         |

10 mg of acid- and alkali-treated fraction IV-4 and 0.5 mg of pig pancreatic kallikrein were incubated in 2 ml of Britton-Robinson's universal buffer. The buffer was prepared from acid mixture (0.04 M phosphoric acid, 0.04 M acetic acid, and 0.04 M boric acid) adjusted to each desired pH value (3.0–10.0) using 0.2 M NaOH in the presence of angiotensinase inhibitors and  $4 \times 10^{-7}$  M SQ 14225, with or without  $5.4 \times 10^{-5}$  M pepstatin at 37 °C for 18 h. The vasoactive substances were extracted from the reaction mixture with hot ethanol and the extract evaporated to dryness under reduced pressure at 45 °C. Bioassays and radioimmunoassays for angiotensin I (AI-RI) and angiotensin II (AII-RI) in the products revealed that kallikrein generated pressor substance from acid- and alkali-treated fraction IV-4 at weakly acidic pH (4.0–6.0). Bioassay values of the pressor substance corresponded well with angiotensin II radioimmunoassay values. Pepstatin showed no inhibitory effect.

**Fig. 1** Mode of pressor activity of kallikrein-generated pressor substance and effects of angiotensin II antagonist. Kallikrein-generated pressor substance was assayed by blood pressure in a female Wistar rat anaesthetized with intraperitoneal sodium amobarbital (100 mg per kg body weight) and ganglion-blocked with subcutaneous pentolinium tartrate (4 mg per kg body weight)<sup>14</sup>. Blood pressure was determined using a catheter inserted into the carotid artery by Hewlett-Packard pressure amplifier (Model 8805 C) and Yokogawa flat-recorder (Type 3051) connected to a Statham p23Db transducer. The samples were injected into a femoral vein, with [1-Sar,8-Ile]-angiotensin II injected into another femoral vein. By continuous infusion of [1-Sar,8-Ile]-angiotensin II at a rate of 50 ng per 0.05 ml per min, pressor activities of [5-Ile]-angiotensin I, [5-Ile]-angiotensin II, and kallikrein-generated pressor substance were inhibited, but that of noradrenaline was not. NE, 20 ng noradrenaline. AI, 6 ng angiotensin I. AII, 2 ng angiotensin II. KT, kallikrein-generated pressor substance.

**Fig. 2** Mode of pressor activity of kallikrein-generated pressor substance and effects of converting-enzyme inhibitor, SQ 14225. SQ 14225 was given by a bolus intravenous injection at a dose of 0.8 mg per kg body weight. It almost completely inhibited pressor action of [5-Ile]-angiotensin I, but not that of [5-Ile]-angiotensin II, kallikrein-generated pressor substance and noradrenaline. Symbols are the same as those in Fig. 1.

substances. Two opposing activities—depressor and pressor—are built into a one-enzyme system and the direction of the reaction may be determined by only a slight pH shift between 5.0 and 8.0. It is suggested that the term 'kinin(s)' be restricted to vasodepressor(s) and the term 'tensin(s)' to vasopressor(s). Based on this nomenclature, 'kinin-tensin enzyme system' may be coined for this type of one-enzyme system with bidirectional circulatory activities, such as the trypsin-(bradykinin and/or angiotensin II) system<sup>6</sup>, and the kallikrein-(kinin and/or angiotensin II) system.

We are attempting to purify and identify the pressor substance released by kallikrein *in vitro*, and examining the possibility that a comparable reaction occurs for the regulation of tissue perfusion *in vivo*. The fact that there must have been cleavage of the Phe-His bond by trypsin and kallikrein suggests that a more fundamental enzymological study with regard to their substrate specificity would be of interest.

This study was supported in part by grants-in-aid from the Japanese Ministry of Education (B-148195 and B-548200), the Fukuoka University Research Institute, and the Rinsho-yakuri-Kenkyushinko Foundation. We thank Miss M. Yanagiuchi and Y. Taniguchi for technical assistance.

## Are opioid peptides co-transmitters in noradrenergic vesicles of sympathetic nerves?

‡Department of Molecular Biology, Wellcome Research Laboratories, Research Triangle Park, North Carolina 27709

Biogenic amines and peptide hormones co-exist in paraneurons<sup>1</sup> or amine precursor uptake and decarboxylation (APUD) cells<sup>2</sup>. Opioid peptide immunohistochemistry occurs in the gland cells and nerve endings of the adrenal medulla<sup>3</sup>, and both dopamine  $\beta$ -hydroxylase (EC 1.14.17.1) and enkephalin-like immunohistochemistry occurs in some small intensely fluorescent and sympathetic ganglion cells<sup>4</sup>. Direct biochemical assays demonstrate opiate-like peptides (OLPs) including Met- and Leu-enkephalin in the adrenal medulla, and the highest specific activity is attained in the purified adrenomedullary chromaffin granule fraction<sup>5</sup>. Chromaffin cells also synthesize enkephalins *de novo*<sup>6</sup>. Adrenal medullae from larger species, including ox and man, contain much more OLP material than those from smaller species such as rodents<sup>5,7</sup>; fortunately so, because only from ox is it practical to purify both chromaffin granules and splenic nerve vesicles at particle purity and yield suitable for chemical composition studies. In ox and man the large dense-cored vesicles (LDVs) comprise 30–50% of the vesicle population in terminals of blood vessels, spleen and vas deferens, equivalent to 80–90% of the total terminal vesicle capacity. For these reasons, we chose bovine splenic nerve in which to investigate the localization of OLPs in the peripheral sympathetic system. Our results, reported here and based on direct biochemical analyses, indicate that OLPs, putative transmitters and noradrenaline probably co-exist in sympathetic C-fibres, which constitute 98% of the bovine splenic nerve. Further, the OLPs and noradrenaline can probably co-exist in the large dense-cored noradrenergic vesicles of this nerve. We believe the obtained 1:60 molar ratio of opioid peptides:noradrenaline to be the highest yet demonstrated for enkephalins in any neurotransmitter organelle or tissue.

The distribution of OLPs in the sucrose-D<sub>2</sub>O density gradient used to purify noradrenergic LDVs is shown in Fig. 1. Of the original peptide activity layered onto the density gradient (SN<sub>15</sub>), 14.6% is soluble and remains above the buffer zone. About 90% of the recoverable, sedimentable OLP material (Table 1) occurs in the heavy vesicle fractions (FIII, fractions 11 and 12) where LDVs equilibrate<sup>8</sup>. Negligible OLPs distribute in the less dense regions of the gradient, including the zone (fractions 6–8) where small dense-cored vesicles typically equilibrate.

The pattern of OLP distribution in the density gradient is almost identical to that of noradrenaline in sedimentable particles<sup>9</sup>, except that about one-third of the noradrenaline readily leaks from the vesicles during tissue homogenization. Dopamine  $\beta$ -hydroxylase also occurs at the highest specific activity in the heavy vesicle peak (Table 1), but about one-third is scattered throughout the gradient at lower buoyant densities<sup>9</sup>. This is explained by the occurrence of 'immature' LDVs from the

proximal end of the nerve, with full enzyme content but low noradrenaline content, and by depletion of matrix material resulting from vesicle rupture during isolation or from previous exocytosis.

Specific activities and recoveries of OLPs at various steps in the purification of LDVs are presented in Table 1 and compared with the analogous data for noradrenaline and dopamine  $\beta$ -hydroxylase. The molar ratio of noradrenaline:OLPs remains ~100:1 and the units of dopamine  $\beta$ -hydroxylase:nmol OLPs at ~1:1 throughout the purification process. The higher purification of OLPs over dopamine  $\beta$ -hydroxylase or noradrenaline (50-fold and 35-fold, respectively) is in keeping with its more restricted localization to LDVs and selective retention.

The stepwise recoveries of OLPs, dopamine  $\beta$ -hydroxylase and noradrenaline vary for particular reasons. Due to their molecular weight of ~500, OLPs should be released from the LDVs only by physical lysis or by exocytosis from nerve terminals, and therefore, relatively little should occur in the soluble phase of the nerve homogenate. However, the peptides are also readily degraded by ubiquitous peptidases<sup>10</sup> and this could be partly responsible for the 25–35% loss reflected in recoverable peptide (Table 1 legend).

**Fig. 1** Opiate-like peptide distribution following density gradient centrifugation. Purified LDVs were prepared from bovine splenic nerve<sup>8,12,13</sup> obtained 10–15 min post mortem using a modified sucrose-D<sub>2</sub>O density gradient sampling procedure<sup>9</sup>. OLPs were preserved in extracts containing 1.0 M acetic acid and measured by displacement of [<sup>125</sup>I]-[D-Ala<sup>2</sup>, D-Leu<sup>5</sup>]enkephalin (0.25 mM; specific activity 2 Ci  $\mu$ mol<sup>-1</sup>) from rat brain membrane receptors<sup>19</sup>. SN<sub>15</sub> is the supernatant obtained from the desheathed splenic nerve homogenate after centrifugation at 10,500g for 15 min. FIII is the purified heavy vesicle fraction containing LDVs and includes fractions (ml) 11 and 12 of the sucrose-D<sub>2</sub>O density gradient based on their similar noradrenaline content per mg protein.

**Table 1** Opiate-like peptide (OLP), noradrenaline (NA) and dopamine  $\beta$ -hydroxylase (D $\beta$ H) content and recovery in purified vesicles from bovine splenic nerve

† Ref. 17.

‡ Refs 14, 18.

In the purified LDV fraction of the density gradient, FIII, the OLP content averages 0.5–0.6 nmol per mg protein. An additional twofold purification is to be expected for the LDVs by differential centrifugation of fraction FIII<sup>9,12,13</sup>. This should result in OLP levels of ~1.0 nmol per mg protein, uncorrected for nonspecifically adsorbed bovine serum albumin, which amounts to at least one-third of the total protein in the vesicle fraction.

Analysis of purified LDV pellet extracts by HPLC reveals three major and several minor peaks with opioid activity (Fig. 2). Two of the major peaks, each representing 30% of the recovered opioid, have retention times identical to those of Met- and Leu-enkephalin standards. The <sup>3</sup>H-Leu-enkephalin internal standard also eluted with a retention time of 19 min. The major opioid component with a retention time of 8 min probably corresponds to oxidized Met-enkephalin<sup>6</sup>. Recovery of opioid activity on the Amberlite column is 48%, compared with 80% for <sup>3</sup>H-Leu-enkephalin internal standard, which is similar to recoveries in acetic acid extracts of adrenomedullary chromaffin

cells<sup>6</sup>. This probably represents the loss of opioid peptides of a larger molecular size than enkephalins<sup>11</sup>. Recovery of OLPs eluted from the Amberlite column and subsequently subjected to HPLC is 70%, similar to the 60% recovery of <sup>3</sup>H-Leu-enkephalin standard. Using the recovery of <sup>3</sup>H-Leu-enkephalin to correct for losses of Met- and Leu-enkephalin during the chromatographic separations, these two peptides comprise 40–50% of the total opioid activity in LDV material.

Table 2 shows data from experiments designed to measure the levels of OLPs in the nerve vesicles as they are transported distally from the nerve cell bodies in the coeliac ganglion to the varicosities in the spleen. The amount of OLPs per gramme fresh nerve weight increases 60–70% in the distal direction and is equal to the increase in protein of the purified vesicle fraction, the latter being a measure of relative vesicle numbers per segment. Similar increases occur in dopamine  $\beta$ -hydroxylase activity and the ATP content, based on nerve segment fresh weight. Thus, OLPs, like dopamine  $\beta$ -hydroxylase and ATP, do not change significantly when expressed on the basis of total

**Fig. 2** High performance liquid chromatographic separation of opiate like peptides from bovine splenic nerve large dense-cored vesicles. An acid extract (2.6 ml) of LDV pellets was applied to a column of Amberlite XAD-2 (2 ml bed volume). The eluate was reappplied to the resin and the resin washed four times with 5 ml of 0.2 M acetic acid. Enkephalins were eluted from the column with 5 ml of 0.2 M acetic acid in methanol. The eluate was evaporated to dryness under  $N_2$  and resuspended in water for application to the HPLC column. HPLC was carried out on a Partisil PXS-10, 10/25 ODS column. After sample application the column was eluted ( $1 \text{ ml min}^{-1}$ ) with 15% acetonitrile/10 mM ammonium acetate, pH 4.2, for 30 min followed by a gradient of 15–50% acetonitrile for 30 min. OLPs, opiate-like peptides; ENK, enkephalin.

protein in the purified LDV fraction from sequential nerve segments. In contrast, noradrenaline content per gram nerve fresh weight increases 273% in the sequential nerve segments. Thus, noradrenaline is synthesized and accumulated by the vesicles during axoplasmic transport, the content increasing ~60% per mg LDV protein<sup>14</sup>. This increase occurs exclusively in the fast release pool of 'newly synthesized' transmitter<sup>15</sup>.

## Differential regulation of the $\alpha_2$ -adrenergic receptor by $Na^+$ and guanine nucleotides

Thomas Michel, Brian B. Hoffman & Robert J. Lefkowitz

Howard Hughes Medical Institute Laboratory, Departments of Medicine (Cardiology) and Biochemistry, Duke University Medical Center, Durham, North Carolina 27710

Many hormones interact with receptors which stimulate the enzyme adenylate cyclase. Less well characterized are those receptors which mediate an inhibition of adenylate cyclase activity<sup>1</sup>. However, guanine nucleotides are clearly important in the regulation of both stimulatory and inhibitory receptors<sup>2</sup>. Monovalent cations, notably  $Na^+$ , regulate many inhibitory receptor systems but apparently not stimulatory receptors<sup>1</sup>. We investigate here the effects of  $Na^+$  and guanine nucleotides on the adenylate cyclase-coupled inhibitory  $\alpha_2$ -adrenergic receptor of the rabbit platelet<sup>3</sup>. Computer modelling of adrenaline competition curves with <sup>3</sup>H-dihydroergocryptine (<sup>3</sup>H-DHE) indicates that adrenaline induces two distinct affinity states of the  $\alpha_2$  receptor—one of higher ( $\alpha_{2H}$ ) and the other of lower ( $\alpha_{2L}$ ) affinity. Guanylyl-5'-yl-imidodiphosphate (Gpp(NH)p) seems to reduce adrenaline affinity by converting the high-affinity state into the low-affinity form of the receptor. In contrast,  $Na^+$  reduces adrenaline affinity at both the high- and low-affinity states of the  $\alpha_2$  receptor while preserving receptor heterogeneity. Thus, guanine nucleotides and  $Na^+$  differ in the manner by which each reduces agonist affinity for the  $\alpha_2$ -adrenergic receptor.

The rabbit platelet's  $\alpha$  receptors were found to be exclusively of the  $\alpha_2$  subtype by the computer modelling of competition curves of the antagonists prazosin and yohimbine with <sup>3</sup>H-DHE<sup>4</sup> which were best described by a model of one class of binding sites with yohimbine much more potent than prazosin (data not shown). This is similar to the situation in human platelets<sup>5</sup>.

Agonist interactions with the rabbit platelet's  $\alpha_2$ -adrenergic receptor are shown in Fig. 1 and Table 1. Without added  $Na^+$  or guanine nucleotides, the adrenaline competition curve with <sup>3</sup>H-DHE yielded a shallow binding isotherm with a slope factor ('pseudo' Hill coefficient) of 0.67 suggesting the presence of heterogeneous binding states. Computer modelling indicated the presence of two classes of binding states with high ( $\alpha_{2H}$ )- and low ( $\alpha_{2L}$ )-affinity states for adrenaline of  $K_d$   $6.3 \times 10^{-9}$  M and  $1.5 \times 10^{-7}$  M, respectively. The addition of Gpp(NH)p (0.1 mM) caused the adrenaline competition curve to shift to lower affinity and to become steep with a slope factor of 1.0. These curves were best fitted by a model with one class of binding states of lower affinity ( $K_d = 1.3 \times 10^{-7}$  M), with this affinity not significantly different from the lower affinity binding state ( $K_d \alpha_{2L} = 1.5 \times 10^{-7}$  M) found in the absence of added Gpp(NH)p. These effects of Gpp(NH)p are very similar to those previously reported for the  $\beta$ -adrenergic receptor in frog erythrocytes<sup>6</sup> and for  $\alpha_2$ -adrenergic receptors in human platelets<sup>5</sup>. In the absence of Gpp(NH)p, 57% of the  $\alpha_2$  receptors are in the  $\alpha_{2H}$  state, the remainder are in the  $\alpha_{2L}$  state, and the ratio  $K_d \alpha_{2L}/K_d \alpha_{2H}$  is 24 (see Table 1). When 0.1 mM Gpp(NH)p is added, all of the  $\alpha_2$  receptors are present in the lower-affinity state ( $\alpha_{2L}$ ); there is no change in the total number of receptors present.

We have previously shown that 100 mM NaCl causes a maximal decrease in agonist affinity at these receptors<sup>7</sup>. In the presence of 100 mM NaCl, competition curves of (–)-adrenaline and <sup>3</sup>H-DHE are shifted to lower overall affinity and increased steepness relative to control curves (Fig. 1, Table 1). The observed slope factor, 0.8, is still, however, significantly less

Binding assays were performed as described in the text. The parameters are derived from the computer modelling of the competition curves shown graphically in Fig. 1. The competition curves are the means of *n* experiments, each done in duplicate. EC<sub>50</sub> refers to the competitor concentration yielding half-maximal inhibition of <sup>3</sup>H-DHE binding. K<sub>dα<sub>2H</sub></sub> and K<sub>dα<sub>2L</sub></sub> refer to the dissociation constants of the high- and low-affinity states, respectively. The fraction of α receptors in these states is shown as %R<sub>H</sub> and %R<sub>L</sub>, respectively. See text for details.

- \* Two-state fit significantly better than one-state fit (*P* < 0.01).
- † Two-state fit not significantly better than one-state fit (*P* > 0.05).
- ‡ Value not significantly different from K<sub>dα<sub>2L</sub></sub> in absence of NaCl and Gpp(NH)p (*P* > 0.05).
- § Value not significantly different from K<sub>dα<sub>2L</sub></sub> in presence of NaCl without added Gpp(NH)p (*P* > 0.05).
- || Slope factor significantly different from 1.0 (*P* < 0.05).
- ¶ Slope factor not significantly different from 1.0 (*P* > 0.05).

than 1.0 (*P* < 0.05). The competition curve is significantly better fitted by a model with two classes of binding states for adrenaline. The proportion of the α<sub>2</sub>-receptor population in the high (R<sub>H</sub>)- and low (R<sub>L</sub>)-affinity states is not significantly changed from the control curve, with %R<sub>H</sub> = 51 and %R<sub>L</sub> = 49. However, adrenaline affinity is reduced at both the high- and low-affinity states. There is a greater relative reduction in affinity at the high-affinity state, as shown by the ratio of K<sub>dα<sub>2L</sub></sub>/K<sub>dα<sub>2H</sub></sub> being 8 in the presence of 100 mM Na<sup>+</sup> compared with a ratio of 24 in the absence of added Na<sup>+</sup>. These results indicate that both Na<sup>+</sup> and Gpp(NH)p reduce agonist affinity, but that Gpp(NH)p abolishes the heterogeneity of agonist binding whereas receptor heterogeneity is maintained in the presence of Na<sup>+</sup>.

Addition of 0.1 mM Gpp(NH)p to adrenaline competition curves in the presence of 100 mM Na<sup>+</sup> causes a further decrease in agonist affinity and an increase in the slope factor to 1.1 (Table 1; Fig. 1). The competition curves in the presence of Gpp(NH)p and Na<sup>+</sup> are best described by a model with a homogeneous class of binding states. The affinity of this state for adrenaline (K<sub>d</sub> = 2.1×10<sup>-6</sup> M) is not significantly different from the K<sub>dα<sub>2L</sub></sub> of 3.2×10<sup>-6</sup> M determined in the presence of Na<sup>+</sup> alone without added Gpp(NH)p. Thus, the effect of Gpp(NH)p in the presence

of Na<sup>+</sup> is apparently to convert receptors in the α<sub>2H</sub> state into the α<sub>2L</sub> state, entirely analogous to the effect of this nucleotide on adrenaline competition curves in the absence of added Na<sup>+</sup>.

In rabbit platelet membranes, prostaglandin E<sub>1</sub> (PGE<sub>1</sub>) causes a 10–12-fold increase in adenylate cyclase activity<sup>3,7</sup>. In the absence of added NaCl, (–)adrenaline (0.1 mM) causes a small but significant decrease (11±6%, data from five experiments) in PGE<sub>1</sub>-stimulated (0.01 mM PGE<sub>1</sub>) adenylate cyclase activity, from 169±20 pmol cyclic AMP per min per mg protein to 150±17 pmol cyclic AMP per min per mg protein. In the presence of 100 mM NaCl, there is a threefold greater maximal inhibition (31±4%) of PGE<sub>1</sub>-stimulated adenylate cyclase activity by adrenaline, from 207±21 down to 143±18 pmol cyclic AMP per min per mg protein (five experiments, significantly greater inhibition than in the absence of Na<sup>+</sup>, *P* < 0.005). The potentiation of adrenaline-mediated inhibition of PGE<sub>1</sub>-stimulated adenylate cyclase by Na<sup>+</sup> is dose dependent, with a half-maximal effect at a Na<sup>+</sup> concentration of 30 mM (data not shown). In the conditions used in this assay, addition of GTP over a wide concentration range (10<sup>-7</sup>–10<sup>-4</sup> M) had no apparent effect on the inhibition of adenylate cyclase by adrenaline in either the presence or absence of Na<sup>+</sup>.

**Fig. 1** Competition curves of <sup>3</sup>H-DHE with (–)adrenaline in the presence and absence of Na<sup>+</sup> and Gpp(NH)p. Isolation of rabbit platelet plasma membranes was as previously described<sup>10</sup> with the exception that the lysate pellet was washed once in resuspension buffer containing 50 mM Tris-HCl and 10 mM MgCl<sub>2</sub>·6H<sub>2</sub>O, pH 7.5. The final resuspension was in this buffer to a protein concentration of 1–3 mg ml<sup>-1</sup>. Radioligand binding assays were in a total volume of 0.2 ml which consisted of 0.025 ml of <sup>3</sup>H-DHE (33 Ci mmol<sup>-1</sup>, NEN) and 0.075 ml of drug in resuspension buffer with NaCl added to yield indicated final concentrations. Incubations (25 °C for 30 min) were started by addition of 0.1 ml of membranes. The assay was terminated by rapid vacuum filtration with a 20-ml wash with resuspension buffer at 25 °C. The concentration of <sup>3</sup>H-DHE in these assays was 4 nM; specific radioligand binding to α receptors was 60–70% of total binding. The affinity of <sup>3</sup>H-DHE binding was 3×10<sup>-9</sup> M in all conditions used in these assays. Computer modelling of competition curves was done as described previously<sup>5,19–23</sup>. For each treatment, competition curves were constructed with each point determined in duplicate. <sup>3</sup>H-DHE binding, as a fraction of binding in the absence of competitor, was computed at each concentration of competitor. Then the results of the individual experiments were meaned and subjected to computer analysis. This analysis provided parameter estimates and standard errors which represent the confidence limits of the computer estimates. The computer program for the data analysis, which is based on the law of mass action, involves nonlinear least squares curve fitting<sup>20</sup> using a generalized model for complex ligand–receptor systems<sup>19</sup>. The computer technique provides an objective evaluation of whether the data are best fitted by a one- or two-receptor-state model. A fit of the data to two states of binding was accepted only if the fit was significantly improved (*P* < 0.05) over that for a one-state fit. The modelling provides values for the affinity constants of the competing ligand for the different states of the receptor and the proportion of the states present when a two-state fit is involved. Slope factors ('pseudo' Hill coefficients) and half-maximal inhibitory concentrations (EC<sub>50</sub>s) in the various experimental conditions were determined using a four-parameter logistic equation, as previously described<sup>22</sup>. Adenylate cyclase assays were performed as described previously<sup>7</sup> with slight modifications. The incubation mixture, in a final volume of 50 μl, consisted of 0.1 mM ATP, 1–2×10<sup>6</sup> c.p.m. of [α-<sup>32</sup>P]ATP and an ATP-regenerating system (in which none of the reagents is Na<sup>+</sup> salts), 50 mM Tris-HCl pH 7.5, 10 mM MgCl<sub>2</sub>, indicated concentrations of NaCl and 1–2 mg ml<sup>-1</sup> membrane protein. PGE<sub>1</sub> at 10<sup>-5</sup> M caused an 8–12-fold stimulation of adenylate cyclase, with half-maximal stimulation by 10<sup>-7</sup> M in either the presence or absence of NaCl. Protein was determined by the method of Lowry<sup>24</sup> using bovine serum albumin as standard. ●, No additions; ▲, +0.1 mM GppNHp; ■, +100 mM NaCl; ◆, +0.1 mM GppNHp + 100 mM NaCl.

The individual and additive reduction in agonist affinity promoted by  $\text{Na}^+$  and guanine nucleotides is characteristic of diverse receptor systems which inhibit adenylate cyclase<sup>1,2,7-12</sup>. Several studies have shown that the presence of one or both of these agents is required for the effective coupling of hormone binding to enzyme inhibition<sup>1,2,13-16</sup>. The present experiments have demonstrated that  $\alpha$ -adrenergic receptor-mediated inhibition of adenylate cyclase is potentiated by  $\text{Na}^+$ . Note that the concentration of  $\text{Na}^+$  yielding half-maximal reduction in agonist affinity ( $40 \text{ mM Na}^+$ )<sup>7</sup> is similar to the  $\text{Na}^+$  concentration yielding half-maximal potentiation of adrenaline-mediated adenylate cyclase inhibition reported here. Our study did not demonstrate a GTP requirement for  $\alpha$ -receptor-mediated adenylate cyclase inhibition. Presumably this reflects the presence of sufficient GTP in the adenylate cyclase assay used in this study to permit adenylate cyclase regulation in the absence of added guanine nucleotides.

These investigations have demonstrated heterogeneity of agonist binding to the  $\alpha_{2L}$  and  $\alpha_{2H}$  states of the  $\alpha_2$ -adrenergic receptor, with the  $\alpha_{2H}$  state seemingly converted into the low-affinity form by guanine nucleotides. These observations resemble the situation described for the  $\beta$ -adrenergic receptor<sup>6</sup>, which promotes the GTP-dependent activation of adenylate cyclase. Applying both biochemical<sup>17</sup> and computer-modelling techniques<sup>6-18</sup> to the  $\beta$ -adrenergic receptor system, it has been proposed that heterogeneity of agonist binding and its regulation by guanine nucleotides are the result of the interaction of the receptor with a GTP-binding nucleotide regulatory protein in the membrane. It seems plausible that the  $\alpha_2$ -adrenergic receptor interacts with an analogous membrane-bound nucleotide regulatory protein<sup>13</sup>, and that this interaction is important in the guanine nucleotide-mediated modulation of agonist affinity states. We have shown that  $\text{Na}^+$  does not abolish heterogeneity of agonist binding, and thus presumably the interaction of  $\alpha$  receptor and nucleotide regulatory protein is maintained even in the presence of  $\text{Na}^+$  as the addition of guanine nucleotides further reduces agonist affinity. In contrast to guanine nucleotides,  $\text{Na}^+$  reduces affinity of both the high- and low-affinity states, and this effect of  $\text{Na}^+$  may be independent of the nucleotide regulatory protein. Perhaps the action of  $\text{Na}^+$  is mediated via the receptor itself or through an interaction with another membrane component distinct from the nucleotide regulatory protein.

In conclusion, these studies have indicated distinctly different roles for guanine nucleotides and  $\text{Na}^+$  in the regulation of the adenylate cyclase-coupled inhibitory  $\alpha_2$ -adrenergic receptor. Although further studies are needed to establish the molecular basis of this differential regulation, the present data suggest that  $\text{Na}^+$  effects may be mediated through independent mechanisms. Understanding the basis of the effects of  $\text{Na}^+$  on either the receptor or other membrane components is relevant to the mechanism of hormone and drug inhibition of adenylate cyclase.

## No junctional communication between epithelial cells in hydra

S. W. de Laat\*, L. G. J. Tertoolen\* & C. J. P. Grimmlikhuijzen†‡

\* Hubrecht Laboratory, International Embryological Institute, Uppsalalaan 8, 3584 CT Utrecht, The Netherlands

† Max-Planck-Institut für medizinische Forschung, Abteilung Biophysik, Jahnstrasse 29, 6900 Heidelberg, FRG

Diffusion gradients of morphogens have been inferred as a basis for the control of morphogenesis in hydra<sup>1,2</sup>, and morphogenetic substances have been found which, on the basis of their molecular weight (MW), should be able to pass gap junctions<sup>3-7</sup>. There have been several reports of the presence of gap junctions between epithelial cells of hydra<sup>8-13</sup>. However, until now, there has been no report published on whether these junctions enable the epithelial cells to exchange molecules of small molecular weight, as has been described in other organisms<sup>14-20</sup>. Therefore we decided to investigate the communicative properties of the junctional membranes by electrophysiological methods and by intracellular-dye iontophoresis. We report here that no electrotonic coupling is detectable between epithelial cells of *Hydra attenuata* in: (1) intact animals, (2) head-regenerating animals, (3) cell re-aggregates, and (4) hydra that have become nerve-free. Furthermore we show that epithelial cells are unable to exchange low-molecular weight fluorescent dyes.

Electrotonic coupling between epithelial cells was measured by conventional intracellular glass microelectrodes<sup>21</sup>. Current pulses were passed and voltages recorded through a single microelectrode. In the intact animal measurements were performed in the head, mid-gastric and foot regions with the two electrodes positioned at short distances (<100  $\mu\text{m}$ ) along the longitudinal or latitudinal axis of the body column. The chances of impalement of epithelial cells were high as this cell type covers most of the surface of the animal<sup>11</sup>. In addition to normal animals, we tested for electrotonic coupling in animals in which we could expect special morphogenetic regulation. In head-regenerating animals electrotonic coupling was monitored at regular intervals in the new head region, starting 30 min after head removal and continuing until new tentacles had appeared (2 days). In another experiment we dissociated hydra into its separate component cells and allowed these to reaggregate, sort, and form new animals<sup>22</sup>. We made measurements all over the aggregates from 2 h after the onset of aggregation until new heads appeared (3 days). Phenotypic variants of hydra that consisted almost totally of epithelial cells were also measured. These so-called nerve-free hydra have similar gap junctions to normal animals<sup>13</sup> and are useful in microelectrode studies as they do not contract spontaneously and offer better chances for impaling epithelial cells only.

By careful impalement with the microelectrodes it was possible to distinguish in intact animals between the ectodermal and the endodermal cells. Figure 1 shows an example of a recording in which the measurement was initially taken from an ectodermal cell, and further penetration resulted in the impalement of an underlying endodermal cell. Ectodermal cells have

‡ To whom correspondence should be addressed.

**Fig. 1** Example of an intracellular recording of the membrane potential and input resistance from epithelial cells of intact normal hydra. Initially an ectodermal cell was impaled, but on further penetration (arrow) the microelectrode moved into an underlying endodermal cell. The recording demonstrates the occurrence of spontaneous fluctuations in membrane potential and input resistance, and the difference in membrane potential between ectodermal and endodermal cells. The input resistance was determined as the ratio between the deflection of the membrane potential and the amplitude of the current pulse. Intracellular voltages were measured and current pulses ( $5 \times 10^{-10}$  A, 500 ms) were passed through a single 3 M KCl-filled glass microelectrode by the use of a bridge circuit to compensate for the electrode impedance. Hydra was kept in a medium composed of 1 mM  $\text{CaCl}_2$ , 0.1 mM  $\text{MgCl}_2$ , 0.1 mM KCl, 0.5 mM  $\text{Na}_2\text{HPO}_4$ , adjusted to pH 7.6 with phosphoric acid. Microelectrode tip potentials ( $<10$  mV) and resistances (20–40 M $\Omega$ ) were determined and compensated in this medium. The electrode properties depend on the ionic strength of the medium. In a control experiment we measured a decrease in tip potential  $<+5$  mV and electrode resistance  $<15$  M $\Omega$  upon changing to a 305 mosm salt solution (about equivalent to the cytoplasm). For this reason membrane potentials and input resistances are expected to be 5 mV more negative and 15 M $\Omega$  greater, respectively, than measured. The mobility of the intact and the head-regenerating animals was reduced during the measurements by adding 2% of the polymer Tylose (Hoechst) to the medium. This allowed continuous recordings of up to 15 min. With nerve-free animals and cell aggregates no Tylose was used.

**Fig. 2** Lack of electrotonic coupling between visibly adjacent ectodermal cells in nerve-free hydra. The figure gives an example of the maximum deflection in membrane potential that could be observed on passing current into an adjacent cell—in nearly all measurements no visible deflection could be observed. In all experiments described in the text the coupling ratio  $V_i/V_j$  was  $<0.04$ , where  $V_i$  and  $V_j$  are the deflection in the membrane potential of cell  $i$  and cell  $j$ , respectively, when a current pulse is passed from cell  $j$  to the grounded medium. Nerve-free hydra were obtained as described<sup>13</sup> and consisted of more than 95% epithelial cells. Conditions as in Fig. 1.

membrane potentials ranging between +5 and -15 mV, whereas endodermal cells have membrane potentials of +25 to +50 mV. This was confirmed by histological examination of fixed animals after marking the impaled cells with Lucifer Yellow CH. The difference in membrane potential between both types of epithelial cells agrees with earlier observations by Kass-Simon and Diesl on isolated epithelial cells<sup>23</sup>. In both types of cell we found spontaneous fluctuations in membrane potential and input resistance (Fig. 1). As no significant differences in membrane potentials and input resistances were found between intact, nerve-free and head-regenerating animals, these data were pooled (Table 1). In early re-aggregates we could not distinguish between ectodermal and endodermal cells. Here the membrane potentials ranged between -15 and +25 mV, with mean value  $+9.1 \pm 5.3$  mV (s.e.m.),  $N = 7$ . The input resistance ranged between 35 and 100 M $\Omega$ , with a mean value of  $68.6 \pm 7.6$  M $\Omega$ ,  $N = 7$  (see also Fig. 1).

Over 100 measurements failed to show electrotonic coupling among ectodermal cells, among endodermal cells, or between ectodermal and endodermal cells in all the experimental conditions, including those in which special morphogenetic regulation

**Fig. 3** Example of a micrograph taken 30 min after iontophoresis of Lucifer Yellow CH into an epithelial cell in nerve-free hydra. No transfer of dye to other cells was observed in any of the experimental conditions applied. Similar results were obtained with fluorescein. The tip of a regular microelectrode was filled with a 3% aqueous solution of Lucifer Yellow CH, whereas the remainder of the electrode system was filled with 3 M LiCl. The dye was introduced iontophoretically into the cell by applying repetitive hyperpolarizing current pulses of  $2 \times 10^{-9}$  A and 1.5 s duration at 0.5 s intervals for 1 min. Fluorescence was observed and photomicrographs were taken as described<sup>27</sup>.

might be expected. Taking into account the resolution limit of our registration system, the coupling ratio  $V_i/V_j$  (see Fig. 2 legend) was always smaller than 0.04. An example of a measurement in nerve-free hydra is shown in Fig. 2.

It might be argued that possible leakage of calcium from the medium into the cells during the impalement might have caused a closure of the gap junctions<sup>20</sup>. To check this, we repeated the measurements in calcium-free medium. We also determined the possible effect of the trans-epithelial potential which normally exists between the gastric cavity and the external medium<sup>24,25</sup>. By insertion of a capillary into the mouth this potential was abolished. In all these circumstances we found normal membrane potentials, input resistances and absence of electrotonic coupling.

In addition to our electrophysiological experiments we studied the exchange of Lucifer Yellow CH (MW, 457) and fluorescein (MW, 330) between epithelial cells. Lucifer Yellow CH<sup>26,27</sup> particularly, was extremely effective for tracing dye coupling due to its excellent spectral properties, its rapid spread through an injected cell, and good retention by the cell during histological processing. In over 75 experiments fluorescent dye was introduced iontophoretically from a glass microelectrode into epithelial cells at different positions along the body column of intact and nerve-free animals. The localization of the dye was

**Fig. 4** Micrographs of 1- $\mu$ m histological sections of normal hydra fixed after iontophoresis of Lucifer Yellow into an ectodermal cell (a) and endodermal cell (b); left: fluorescence, right: phase contrast (unstained). Conditions as in Fig. 3. The animals were fixed in 4% formaldehyde for 24 h at 4°C, dehydrated in dimethoxypropanal (DMP) for 1 h, embedded in Spurr low-viscosity embedding medium by placing in Spurr/DMP (1:1) for 5 h, Spurr/DMP (3:1) for 12 h and Spurr only for 8 h. Polymerization was at 60°C for 12 h.

monitored by fluorescence microscopy up to 1 h after application. Throughout this time the fluorescence remained definitively located within a single cell, without detectable transfer to neighbouring cells (Fig. 3). Some of the animals were fixed after introduction of Lucifer Yellow CH into a number of epithelial cells and examined after histological processing (Fig. 4). From observation of serial 1- $\mu$ m sections we made the following conclusions: (1) there was no transfer of the dye between epithelial cells, (2) the absence of electrotonic and dye coupling was not due to positioning of the micro-electrode in the large vacuoles—iontophoretically applied Lucifer Yellow CH was definitively located within the cytoplasm, (3) the impalement did not cause apparent cell damage, (4) ectodermal and endodermal cells have different membrane potentials (see above).

Our observations show that the epithelial cells in hydra are not able to exchange ions and fluorescent dyes of low molecular weight. We conclude that: (1) gap junctions between epithelial cells of hydra, observed by electron microscopy, do not function as communicative intercellular junctions—they might be of a primitive type, involved in the formation of connective junctions, (2) morphogenetic substances probably diffuse via the extracellular space, (3) nerve-free hydra which are still able to contract on electrical or mechanical stimulation<sup>28</sup> cannot conduct the contraction pulse along electrotonically coupled epithelial cells—they may use paracrine communication.

We thank Dr W. W. Stewart for his gift of Lucifer Yellow CH, Dr H. C. Schaller for her interest, and the Deutsche Forschungsgemeinschaft (Scha 253/6) for financial support.

**Table 1** Membrane potential and input resistance in hydra epithelial cells

|          | Membrane potential (mV)  | Input resistance (M $\Omega$ ) |
|----------|--------------------------|--------------------------------|
| Ectoderm | $-2.5 \pm 1.2$ (N = 16)  | $38.8 \pm 4.7$ (N = 16)        |
| Endoderm | $+36.0 \pm 1.3$ (N = 40) | $45.5 \pm 2.9$ (N = 40)        |

Mean number of cells  $\pm$  s.e.m. are given. The spontaneous fluctuations in each cell (see Fig. 1) were averaged by taking values of the membrane potential and the input resistance at 1-min intervals.

## Receptor binding and internalization of immobilized transcobalamin II by mouse leukaemia cells

Kiyoshi Takahashi\*, Mehdi Tavassoli\* & Donald W. Jacobsen††

Departments of \*Clinical Research and †Biochemistry, Scripps Clinic and Research Foundation, La Jolla, California 92037

Membrane transport of vitamin B<sub>12</sub> (cyanocobalamin; Cbl) into mammalian cells is mediated by the serum protein transcobalamin II (TCII)<sup>1–3</sup>. In mouse leukaemia L1210 cells, TCII-Cbl binds to membrane receptors in a rapid, temperature-independent step and is internalized by a slow, temperature-dependent process<sup>4</sup>. To delineate the location of receptors on these cells, we have constructed a visual probe by covalently coupling purified TCII-Cbl to submicrometre latex particles<sup>5</sup> (minibeads). We report here that when L1210 cells are incubated with minibeads containing TCII-Cbl at 4°C and examined by scanning electron microscopy (SEM), the particles are found attached predominantly to microvilli. Incubation of the cells at 37°C results in the internalization of the minibeads. As visualized by transmission electron microscopy (TEM), this endocytotic process seems to occur in clathrin-coated pits and vesicles<sup>6,7</sup> at the cell surface.

Recent work has demonstrated that cultured L1210 cells attach tightly to large (70  $\mu$ m) Sepharose beads coated with Cbl-TCII<sup>8</sup>. Although the binding of numerous cells (~150 cells per bead) somewhat obscured the contact zone between the bead and the cell, it was apparent that cellular microvilli made intimate and extensive contact with the bead surface. To identify specific receptor areas for TCII-Cbl on L1210 cell surfaces and perhaps confirm the apparent role of microvilli in the transport process, we have repeated these experiments using small (0.35  $\mu$ m) latex particles derivatized with TCII-Cbl. The latter were prepared by a method modified from Weston and

† To whom correspondence should be addressed.

**Fig. 1** Synthesis and structure of the receptor probe L~TCII-Cbl. Amide-modified polystyrene latex particles (0.35  $\mu\text{m}$ ; Dow) were suspended to 5% (w/v) in 0.1 M  $\text{NaHCO}_3$  (pH 8.0) and 8% glutaraldehyde was added to a final concentration of 5% (step a). After 24 h at 37 °C, excess glutaraldehyde was removed by dialysis against 0.1 M  $\text{NaHCO}_3$  (pH 8.8) for 24 h at 4 °C. Rabbit serum TCII-Cbl (100  $\mu\text{g}$ ), purified by the method of D.W.J. *et al.*<sup>10</sup>, was added to 1 ml of a 0.1% suspension of the glutaraldehyde-modified minibeads in 0.1 M  $\text{NaHCO}_3$  (pH 8.8) (step b). After 6 h at room temperature, the preparation was treated with 0.2 M  $\text{NaBH}_4$  for 15 min at 4 °C (step c). The L~TCII-Cbl minibeads were pelleted by centrifugation (40,000g for 20 min) and washed three times with phosphate-buffered saline (pH 7.4).

**Fig. 2** Binding of L~TCII-Cbl to microvilli of L1210 cells. Cultured L1210 cells were suspended for 2 h (4 °C) with 0.04% L~TCII-Cbl in RPMI 1640 medium containing 5% fetal bovine serum, collected by centrifugation (150g for 7 min) and washed twice with serum-free medium. A drop of cell suspension was placed on a round coverslip pretreated with poly-L-lysine (50  $\mu\text{g ml}^{-1}$ ) and fixed in modified Karnovsky's solution containing 0.125 M cacodylate buffer (pH 6.8) for 7 min. The coverslip was then rinsed three times with 0.125 M cacodylate (pH 7.3) and postfixed in similarly buffered 2%  $\text{OsO}_4$  for 15 min at room temperature. After dehydration and displacement in Freon 113, the cells were critical point-dried and sputter coated with platinum-palladium.  $\times 18,000$ , inset  $\times 4,500$ .

**Fig. 3** Binding capacity of L1210 cells for L~TCII-Cbl and control minibeads. Incubation conditions were as described in Fig. 2 legend except that time and temperature varied as indicated. Each circle represents the number of minibeads bound per cell. Scoring was made on SEM prints of cells randomly selected at low magnification ( $\times 500$ ; well below the resolution required to detect minibeads) and then photographed at higher magnification ( $\times 6,000$ ). These data represent two separate preparations of L~TCII-Cbl. Control studies used plain (L) or amide-modified (L~NH<sub>2</sub>) latex, or minibeads on which TCII-Cbl was replaced by glycine (L~Gly), myoglobin (L~Myo) or the non-TCII Cbl-binder from chicken serum (L~CS-Cbl).

Avrameas<sup>9</sup> to form the receptor probe L~TCII-Cbl shown in Fig. 1. The same method was used to prepare control minibeads derivatized with glycine, myoglobin or the non-TCII Cbl-binder from chicken serum.

Cultured L1210 cells were incubated with L~TCII-Cbl at 4 or 37 °C for 0.5, 2 or 4 h. The cells were then collected, washed, fixed and processed for SEM and TEM. As shown in Fig. 2, SEM revealed extensive interaction between L~TCII-Cbl and microvilli. In some cases, these minibeads decorated the entire length of the microvillus, suggesting a localized and highly concentrated region of TCII-Cbl receptors. Minibead clusters were occasionally seen closer to the cell surface, but shorter microvilli could have been responsible for this effect. Quantitative data (Fig. 3) obtained from SEM prints indicated that minibeads containing TCII-Cbl bound equally well at 4 or 37 °C, averaging 12 and 10 per cell, respectively. The specificity of the interaction is also shown in Fig. 3. Thus, unmodified minibeads or minibeads derivatized with glycine, myoglobin or the non-TCII Cbl-binder from chicken serum did not bind to L1210 cells.

When cells were incubated with L~TCII-Cbl at 37 °C and then examined in sections using TEM, various stages of internalization were visualized (Fig. 4). Small clusters of minibeads appeared at the cell surface and were embedded in coated pits

and coated vesicles. The latter were morphologically similar to vesicles containing the structural protein clathrin, but were somewhat larger ( $\sim 0.35 \mu\text{m}$ ) than those commonly encountered in adsorptive endocytosis ( $0.05\text{--}0.25 \mu\text{m}$ )<sup>6</sup>.

These studies provide visual evidence for the localization of TCII-Cbl receptors on the microvilli of L1210 cells and suggest that the complex is internalized at the surface of the cell. Although it is not clear how the receptor complex reaches the surface for endocytosis, at least two mechanisms can be invoked: either the microvilli retract and become contiguous with the surface, or the receptor complex laterally diffuses along the

**Fig. 4** Internalization of L-TCII-Cbl by L1210 cells. Incubation conditions were as described in Fig. 2 legend except that the temperature was  $37^\circ\text{C}$ . Cells were prepared, fixed and dehydrated as for SEM, and then embedded in Spurr resin and thin-sectioned. After staining with uranyl acetate and lead citrate, preparations were examined by TEM. *a* Shows several minibeads on the cell surface, two of which seem to be in the process of internalization.  $\times 21,000$ . *b* Shows a minibead within a vesicle which seems to be coated by clathrin.  $\times 15,000$ . *c* Shows two minibeads completely internalized within a common vesicle.  $\times 10,000$ .

microvilli and on to the surface for subsequent endocytosis. In either case, internalization of L-TCII-Cbl seems to occur via clathrin-coated pits and vesicles in a temperature-dependent fashion.

The plasma tripeptide glycyl-L-histidyl-L-lysine (GHL), when added at nanomolar concentrations to a wide group of cultured systems, produces a disparate set of responses ranging from the stimulation of growth and differentiation to outright toxicity<sup>1-3</sup>. Such diverse actions imply that this tripeptide mediates some basic biochemical function common to many types of cells and organisms. During the isolation of GHL we found the compound to co-isolate through a number of steps with approximately equimolar copper and about 1/5 molar iron<sup>4</sup>. Maximal effects on hepatoma cells (HTC<sub>4</sub>) were seen when the peptide was added with copper and iron to the growth medium<sup>1</sup>. Structure-function studies revealed that several tripeptides with a histidyl-lysyl linkage were nearly as active as GHL<sup>1</sup>. The association of GHL with copper and a homology similarity between the tripeptide and the copper transport sites on albumin and  $\alpha$ -fetoprotein, where the cupric atom is bound to a histidyl residue adjacent to a basic residue, suggested that GHL may act as a copper transport factor<sup>4</sup>. We report here that the tripeptide readily forms complexes with copper(II) and enhances the uptake of the metal into cultured hepatoma cells.

GHL was synthesized by coupling *N*<sup>ε</sup>-t-butyloxycarbonyl-*N*<sup>im</sup>-benzyloxycarbonyl-L-histidine to benzyl *N*<sup>ε</sup>-benzyloxycarbonyl-L-lysine using a mixed anhydride procedure involving isobutyl chloroformate and *N*-methyl morpholine to yield benzyl *N*<sup>ε</sup>-t-butyloxycarbonyl-*N*<sup>im</sup>-benzyloxycarbonyl-L-histidyl-*N*<sup>ε</sup>-benzyloxycarbonyl-L-lysinate. The protected dipeptide was dissolved in methanol saturated with HCl to cleave the t-butyloxycarbonyl protecting group and to precipitate benzyl *N*<sup>im</sup>-benzyloxycarbonyl-L-histidyl-*N*<sup>ε</sup>-benzyloxycarbonyl-L-lysinate hydrochloride. Neutralization of this salt with triethyl amine gave the free dipeptide amine, which on joining to *N*<sup>ε</sup>-benzyloxycarbonylglycine by a mixed anhydride method, formed benzyl *N*<sup>ε</sup>-benzyloxycarbonylglycyl-*N*<sup>im</sup>-benzyloxycarbonyl-L-histidyl-*N*<sup>ε</sup>-benzyloxycarbonyl-L-lysinate. Hydrogenolysis of this fully protected compound produced the free peptide and chromatography on silica gel yielded crystalline GHL that had satisfactory microanalytical and amino acid analyses, as well as spectral data (IR and NMR).

When GHL was added to hepatoma (HTC<sub>4</sub>) cells, which had been cultured in low serum (0.75%) fetal calf serum, it was observed that the tripeptide elevated copper uptake in a dose-dependent manner from 10 to 200 ng ml<sup>-1</sup>. Higher concentrations of the compound were less effective and very high concentrations of the tripeptide (10  $\mu\text{g ml}^{-1}$ ) were inhibitory to copper uptake into the cells. When the compound was added at 200 ng ml<sup>-1</sup>, copper uptake increased approximately 2.4-fold after 4 h incubation (Fig. 1). The tripeptide's effect was rapid and the rise in the intake of copper at 30 min was 50% of the 4-h value. Addition of the constituent amino acids of GHL at a molar ratio 300-fold greater than that found in the parent compound at 200 ng ml<sup>-1</sup> did not alter the rate of copper transfer (Fig. 1). By contrast, the tripeptide had no significant effect on the transport of ferrous (<sup>59</sup>Fe) iron into the cells. These

results suggest that GHL transports copper, and perhaps other related metals, into cells in culture.

This possibility is further supported by evidence that the tripeptide readily forms chelates with cupric ions. A single crystal X-ray diffraction study of a GHL-Cu complex showed the existence of a tridentate bonding structure involving the N-terminal group of glycine, the nitrogen atom of the first amide bond, and the imine nitrogen atom of the imidazole ring of histidine. The  $\epsilon$ -terminal amine group on the lysine side chain remains free and is not bound to the copper atom (Fig. 2). The electron paramagnetic resonance spectrum (EPR) of the peptide was determined on a frozen, aqueous solution (0.55 mM) in the presence of Cu(II) (0.50 mM) at 77 K and 9.073 GHz. The magnetic parameters obtained from the axial spectrum were  $A_{\parallel}$  210 G,  $g_{\parallel}$  2.335, and  $g_{\perp}$  2.057. These data indicate that the  $d_{x^2-y^2}$  orbital is the highest d-orbital, a result consistent with strong interactions between a copper ion and four ligands in a near-equatorial arrangement. The super-hyperfine structure present in the EPR spectrum supported the involvement of the copper with at least one nitrogen donor atom in a near-planar coordination. Electron spin echo studies confirmed the coordination of imidazole to copper and there was no indication from the EPR spectrum for dipolar interactions between two adjacent copper atoms<sup>5</sup>. The combined X-ray and EPR results are consistent with the idea of a GHL-Cu complex in solution that is monomeric in nature.

These experiments at low-serum conditions of cell culture suggest an increase in copper transport serves as a mechanism for the action of GHL and may explain the range of responses to

**Fig. 2** Structure of GHL-Cu crystals. X-ray analysis indicates that the N-terminal group of glycine, the adjacent nitrogen in the first amide linkage of the peptide chain and the unprotonated nitrogen of the imidazole ring of histidine form bonds to copper. EPR measurements suggest that the GHL-Cu complex exists as a monomeric species in dilute solution. The detailed interpretation of the X-ray and EPR data will be published elsewhere.

**Fig. 1** Effect of glycyl-L-histidyl-L-lysine (GHL) on the uptake of <sup>64</sup>Cu and <sup>59</sup>Fe into hepatoma cells in culture. Hepatoma (HTC<sub>4</sub>) cells were cultured for 3 days in 90% Eagle's basal medium plus 10% Swim's S-77 medium and 0.7% fetal calf serum in plastic T-flasks (25 cm<sup>2</sup>, 10<sup>6</sup> cells per flask) by methods previously detailed<sup>1</sup>. GHL was then added to the cultures at the indicated dosages. <sup>64</sup>Cu (1  $\mu$ Ci, 4.9 Ci per g) was added and glycine, histidine and lysine were present in 300-fold molar excess over GHL at 200 ng ml<sup>-1</sup>. The cells were incubated for 4 h at 37 °C, the media removed, and the cells washed four times with phosphate buffer saline, pH 7.4 (Gibco), at 0 °C, incubated in 0.01% trypsin for 15 min, and then cells were removed from the flask. The hepatoma cells were centrifuged at 2,000g for 30 min at 0 °C then homogenized in distilled water. The cellular debris was removed by centrifugation at 10,000g for 10 min and aliquots of the supernatant, representing copper from the cellular cytosol, counted by normal scintillation counting methods<sup>21</sup>. The cellular uptake of radiolabelled Cu at the various dosages of GHL ( $\pm$ s.d.) for six experiments is given in Fig. 1. In the complete absence of serum, GHL was only one-quarter as active in stimulating Cu uptake. The control Cu uptakes at 0.5, 1 and 2 h were, respectively, 51%, 72% and 84% of the 4-h value. The uptake of radiolabelled Fe (1  $\mu$ Ci per flask, 6.2 Ci per g) was determined in the same way as for Cu.

the compound. Synthetic tripeptide, when added to culture media at concentrations of 10–200 ng ml<sup>-1</sup>, has been found to: (1) enhance the growth of hepatoma cells<sup>3</sup>, thyroid follicular cells<sup>6</sup> and T-strain mycoplasma<sup>7</sup>; (2) stimulate the growth and differentiation of *Ascaris* larvae<sup>8</sup>, lymphocytes<sup>9</sup> and neurones<sup>10,11</sup>; (3) assist the establishment in culture of 19 cancer cell lines from human tumours<sup>12</sup>; (4) raise the viability of eosinophils<sup>13</sup>, endometrial cells<sup>14</sup>, fibroblasts<sup>15</sup>, kidney cells<sup>16</sup>, liver cell and organ cultures<sup>3,17</sup>, macrophages<sup>18</sup>, mast cells<sup>19,20</sup> and placental organ cultures<sup>21</sup>; (5) inhibit the growth of glial<sup>10</sup> and L929 cells<sup>22</sup>; and (6) increase antibody cytotoxicity towards parasitic worms (*Schistosoma mansoni*)<sup>23</sup>. Different patterns of cellular response to an increased copper(II) intake would rationalize the range of biological effects observed by various workers.

Furthermore, these results clearly delineate a structural model for a molecule that delivers transition metals to cellular receptors. The first two residues of the GHL molecule are involved in the bonding of the copper, whereas the side chain of lysine may be involved in the recognition of receptors that function in the uptake of the copper into cells. This possibility is further strengthened by the obvious analogies to the copper transport sites on plasma albumin or, in the fetus, on  $\alpha$ -fetoprotein, in which the histidyl residue that binds the copper is immediately adjacent to either a lysyl or an arginyl residue.<sup>4</sup> These considerations imply that the combination of a histidyl unit next to a basic residue constitutes a biologically active structure critical for the uptake of copper into cells.

**Fig. 1** EPR spectrum of sub-mitochondrial particles ( $70 \text{ mg ml}^{-1}$  in  $0.25 \text{ M}$  sucrose,  $50 \text{ mM}$  morpholinopropane sulphonic acid buffer,  $\text{pH } 7.0$ ) reduced for  $3 \text{ min}$  at  $20^\circ\text{C}$  with  $5 \text{ mM}$  ascorbate in the presence of  $10 \mu\text{M}$   $N,N,N',N'$ -tetramethyl- $p$ -phenylenediamine,  $20 \mu\text{M}$  cytochrome  $c$  and  $4 \text{ mM}$  KCN. The EPR spectra were measured at  $36 \text{ K}$ ,  $5 \text{ mW}$  microwave power,  $9.33 \text{ GHz}$  frequency and  $6.3 \text{ G}$  modulation amplitude. The spectra plotted were 20–25 times scan averaged and corrected for differences in tube diameter and protein concentration. The top spectrum is that of untreated particles and the middle one after incubation with  $10 \text{ mM}$  BAL (2,3-dimercaptopropanol) and shaking in air for  $30 \text{ min}$  at  $36^\circ\text{C}$  (ref. 11). The bottom spectrum is the difference: control minus BAL-treated.

## Identification of the BAL-labile factor

E. C. Slater & S. de Vries

Laboratory of Biochemistry, BCP Jansen Institute, University of Amsterdam, Plantage Muidergracht 12, 1018 TV Amsterdam, The Netherlands

One of us has previously reported<sup>1</sup> that treatment of the Keilin and Hartree heart-muscle preparation<sup>2</sup> with 2,3-dimercaptopropanol (BAL), in the presence of air, leads to the complete inactivation of the succinate oxidase system with little if any effect on the activities of succinate dehydrogenase (until more than half the BAL was oxidized) or cytochrome  $c$  oxidase. The inactivation of the complete succinate oxidase system requires the oxidation of BAL by air in the presence of the enzyme. It is not caused by  $\text{H}_2\text{O}_2$  or BAL disulphides produced during the oxidation of BAL. Spectroscopic studies identified the block as lying between cytochromes  $b$  and  $c$ . It was suggested that a BAL-labile factor is present which transfers electrons from cytochrome  $b$  to cytochrome  $c$  and which is destroyed by coupled oxidation with BAL. The factor is also required for NADH oxidation<sup>3</sup>. Subsequent work showed that it is not identical with cytochrome  $c_1$  (ref. 4), myoglobin present in the preparation<sup>5</sup> or the antimycin-binding site<sup>6</sup>. We report here that this factor is identical to the iron-sulphur protein in the central portion of the respiratory chain first identified by Rieske<sup>6</sup>.

The following clues led us to this identification: (1) Deul and Thorn's observation<sup>5</sup> that, whereas after either BAL treatment or addition of antimycin electron flow between cytochromes  $b$  and  $c$  is blocked, the addition of antimycin to BAL-treated preparations causes a block in the reduction of cytochrome  $b$ . (2) Trumpower's observation<sup>7</sup> that in preparations of succinate/cytochrome  $c$  oxidoreductase from which Racker's 'oxidation factor'<sup>8</sup> has been extracted electron transfer between cytochromes  $b$  and  $c_1$  is impaired, but that in the presence of antimycin the reduction of cytochrome  $b$  is blocked. (3) The recent identification by Trumpower<sup>9</sup> of the active principle in Racker's preparations of oxidation factor as Rieske's iron-sulphur protein.

Direct evidence that BAL specifically destroys the Rieske iron-sulphur protein has now been obtained by electron paramagnetic resonance (EPR) spectrometry.

The EPR spectrum of sub-mitochondrial particles reduced with ascorbate in the presence of tetramethyl- $p$ -phenylenediamine, cytochrome  $c$  and cyanide (Fig. 1) shows lines characteristic of the Rieske iron-sulphur protein:  $g_z = 2.03$ ,  $g_y = 1.89$  and  $g_x = 1.80$ . There is an additional line at about  $1.94$  derived from partial reduction of one of the iron-sulphur clusters associated with succinate dehydrogenase, and a free radical

at about  $g = 2.0$  derived from the semiquinone of ubiquinone and from ascorbate. (The broad line at about  $2.1$  is probably due to contaminating copper.) After BAL treatment, the signals of the Rieske iron-sulphur protein completely disappeared. The residual signals are due to the free radical and the  $g_y$  and  $g_z$  lines of the iron-sulphur cluster of succinate dehydrogenase. The difference spectrum shows the three lines characteristic of the Rieske iron-sulphur protein.

Figures 2 and 3 show similar spectra obtained after reduction with succinate and  $\text{NADH} + \text{Na}_2\text{S}_2\text{O}_4$ , respectively. Although the  $g_z$  and  $g_y$  lines are now overshadowed by signals from other iron-sulphur clusters reduced at the lower potentials, the difference spectra (control minus BAL-treated) are in both cases dominated by the signals of the Rieske cluster. The complete elimination of the broad  $g_x$  line at  $1.80$ , which is characteristic of the Rieske iron-sulphur protein, is particularly clear. Lines at  $g = 1.92$  and  $2.01$  in the difference spectrum in Fig. 3 are

**Fig. 2** EPR spectrum of sub-mitochondrial particles reduced for  $10 \text{ min}$  at  $30^\circ\text{C}$  with  $20 \text{ mM}$  succinate in the presence of  $20 \mu\text{M}$  cytochrome  $c$  and  $4 \text{ mM}$  KCN. Conditions were as in Fig. 1 legend, except that the gain used for the direct spectra was  $1/1.6$  times that in Fig. 1, and that in the difference spectrum was twice that in the direct spectrum.

**Fig. 3** EPR spectrum of sub-mitochondrial particles reduced for 10 min at 20 °C with 2 mM NADH (pH 7.2) and dithionite in the presence of 20  $\mu$ M cytochrome *c* and 4 mM KCN. Conditions were as in Fig. 1 legend, except that the gain used for the direct spectra was 1/3.2 times that in Fig. 1, and that in the difference spectrum was three times that in the direct spectrum.

probably due to destruction by BAL treatment of an iron-sulphur protein in the outer membrane of the mitochondrion, fragments of which are present in sub-mitochondrial particles<sup>10</sup>.

Figure 3 shows that, although the mitochondrial inner membrane contains about 10 different iron-sulphur clusters, only that belonging to the Rieske protein is destroyed by BAL

treatment of sub-mitochondrial particles, thus confirming the specificity of BAL treatment<sup>11</sup>.

The nature of the chemical reaction between BAL, oxygen and the iron-sulphur protein is not established. It is possible that a disulphide bridge is formed between BAL and one of the cysteine molecules or the inorganic sulphur that is bound to the iron atom in the iron-sulphur cluster. The specificity of the BAL action may be due to the relative accessibility of this strongly hydrophilic compound to the Rieske iron-sulphur cluster.

We conclude that the BAL-labile factor is identical to the Rieske iron-sulphur protein; the oxidation factor has also been identified with this protein<sup>9</sup>. BAL treatment is therefore a useful technique for specifically eliminating the Rieske iron-sulphur cluster from the respiratory chain of sub-mitochondrial particles.

## 1,25-Dihydroxycholecalciferol stimulation of a mitochondrial protein in chick intestinal cells

Adrian N. Hobden\*, Marilyn Harding & D. Eric M. Lawson

Dunn Nutritional Laboratory, University of Cambridge and Medical Research Council, Milton Road, Cambridge CB4 1XJ, UK

The steroid hormone 1,25-dihydroxycholecalciferol (1,25-(OH)<sub>2</sub>D<sub>3</sub>) stimulates the absorption of dietary calcium by the small intestine of animals although the exact mechanism by which this is achieved remains unclear. However, it has long been known that a soluble, calcium-binding protein (CaBP), is produced in large amounts in the cytoplasm of the intestinal cells of animals after *in vivo* administration of vitamin D<sub>3</sub> or 1,25-(OH)<sub>2</sub>D<sub>3</sub> (refs 1, 2). We report here that 1,25-(OH)<sub>2</sub>D<sub>3</sub> administered *in vivo* to rachitic chickens also stimulates production of another protein with molecular weight (MW) 39,000–42,000 which is insoluble in the absence of detergent, is found in the outer mitochondrial membrane and is produced in advance of maximum calcium transport.

Synthesis of CaBP is not optimal until after maximum stimulation of calcium transport by 1,25-(OH)<sub>2</sub>D<sub>3</sub> (ref. 3)—there is significant stimulation of calcium transport before any CaBP can be detected in the intestinal cell. Thus CaBP cannot have a direct effect on calcium transport and other factors which are responsive to *in vivo* administration of 1,25-(OH)<sub>2</sub>D<sub>3</sub> have been sought. Two such factors, proteins of MW 45,000 and 84,000, have been identified in the intestinal brush borders of chickens<sup>4,5</sup>. However, only small quantities of these proteins

were produced after administration of 1,25-(OH)<sub>2</sub>D<sub>3</sub> possibly indicating additional rather than *de novo* synthesis. The function of these proteins is unknown although any role for them in calcium uptake would possibly be at the level of absorption of calcium from the intestinal lumen into the cytoplasm. Once calcium has crossed the intestinal brush border membrane, it has to be transported across the cell to the basal membranes and then into the capillaries. We therefore looked for any changes in protein composition of intestinal mitochondria following *in vivo* administration of 1,25-(OH)<sub>2</sub>D<sub>3</sub> to rachitic chickens.

At various times following administration of 125 ng of 1,25-(OH)<sub>2</sub>D<sub>3</sub>, the rachitic chickens were killed and slices of their everted jejunum incubated in medium containing [<sup>14</sup>C]leucine. Mitochondria were isolated from the slices and their proteins electrophoresed through SDS gels together with proteins (labelled with [4,5-<sup>3</sup>H]leucine) from the intestinal mitochondria of 1,25-(OH)<sub>2</sub>D<sub>3</sub>-deficient chickens. The gels were sliced and the radioactivity in each slice determined. Examination of the ratio of <sup>14</sup>C:<sup>3</sup>H in each slice revealed that an extra protein (or additional amounts of a protein) was being produced in the birds subjected to 1,25-(OH)<sub>2</sub>D<sub>3</sub> administration (Fig. 1). The level of synthesis of this protein was quantified from the double-label plot<sup>6</sup> (Fig. 1) and a time course of synthesis determined (Fig. 2). This additional mitochondrial protein maximally accounted for over 7% of total mitochondrial protein synthesis (Fig. 2). Comparison with the time courses for other events which follow *in vivo* administration of 1,25-(OH)<sub>2</sub>D<sub>3</sub> (refs 3, 4) reveals that maximum production of this mitochondrial protein (at 4 h) occurred before maximum calcium transport (at 8 h) and well before maximum synthesis of CaBP (Fig. 3). Although the MW and the time course of appearance (Fig. 3) were similar to those of a protein previously observed in intestinal brush borders<sup>4,5</sup> the mitochondrial protein was produced in greater amounts (P. Wilson, personal communication), had a consistently smaller MW (39,000–42,000) and did not behave like actin (putatively identified as the brush border protein<sup>5</sup>) on gel electrophoresis in 8 M urea. We suggest therefore that the mitochondrial protein is a novel product of the

intestinal cells which is produced following *in vivo* administration of  $1,25\text{-(OH)}_2\text{D}_3$ .

Partial fractionation of the intestinal mitochondria into inner membrane, outer membrane and soluble protein fractions was achieved by sonication and sucrose density-gradient centrifugation<sup>7</sup>. In this way we showed that the novel mitochondrial protein had a distribution between the fractions similar to the enzyme rotenone-insensitive NADH-cytochrome *c* reductase (Fig. 4), a marker for the outer mitochondrial membrane<sup>7</sup>. Thus it seems that this protein is a constituent of the outer mitochondrial membrane. Little or no protein was found in the soluble fraction and it could not be solubilized unless a detergent (0.1% v/v Triton X-100) was present in the buffer.

Mitochondria from a wide variety of tissues can accumulate large amounts of calcium<sup>8-10</sup> and they have long been thought to be involved in calcium transport across intestinal cells<sup>11,12</sup>. However, the influence of vitamin  $\text{D}_3$  and  $1,25\text{-(OH)}_2\text{D}_3$  on the

**Fig. 2** Time course of synthesis of mitochondrial protein. Slices of everted chick jejunum from vitamin D-deficient chicks or those dosed at various times before death with 125 ng of  $1,25\text{-(OH)}_2\text{D}_3$  were incubated with radioactive leucine and their mitochondria prepared as described in Fig. 1 legend. Mitochondrial proteins from chicks dosed with  $1,25\text{-(OH)}_2\text{D}_3$  at a certain time before death were mixed with those from vitamin D-deficient chicks electrophoresed and counted as described previously (Fig. 1 legend). The level of  $^{14}\text{C}$  radioactivity observed in the peak at MW 39,000–42,000 in a difference plot<sup>6</sup> (see Fig. 1b) was estimated and expressed as percentage of total  $^{14}\text{C}$  on the gel.

**Fig. 1** Mitochondrial proteins synthesized in intestinal slices from  $1,25\text{-(OH)}_2\text{D}_3$ -dosed or deficient chickens. Flasks containing 0.5 g of everted chick jejunal slices (about 2 mm thick) were incubated in 10 ml of Krebs Improved Ringer 1 medium<sup>18</sup> for 2 h with shaking in  $\text{O}_2/\text{CO}_2$  (19:1) atmosphere at  $37^\circ\text{C}$ . Slices from vitamin D-deficient chicks or those dosed 4 h before death with 125 ng of  $1,25\text{-(OH)}_2\text{D}_3$  were incubated with  $[4,5\text{-}^3\text{H}]\text{leucine}$  (125  $\mu\text{Ci}$ ) and  $[U\text{-}^{14}\text{C}]\text{leucine}$  (25  $\mu\text{Ci}$ ), respectively. After incubation the slices were washed several times with 0.9% w/v NaCl and their mitochondria isolated<sup>19</sup>. Mitochondria from dosed and deficient chicks were mixed (50,000–100,000 d.p.m. of  $^3\text{H}$ , 25,000–50,000 d.p.m. of  $^{14}\text{C}$  and  $\sim 0.5$  mg protein) and dissociated before electrophoresis by heating at  $70^\circ\text{C}$  for 30 min in a solution containing dithiothreitol (15  $\text{mg ml}^{-1}$ ), SDS (10  $\text{mg ml}^{-1}$ ), Tris (12  $\text{mg ml}^{-1}$ ) and glycerol (0.1 ml). After electrophoresis in SDS-polyacrylamide<sup>5</sup> the gel was washed for several hours in acetic acid/propan-2-ol/water (2:5:13) by volume and cut into 1-mm sections. Each slice was treated with 0.5 ml 90% (v/v) NCS tissue solubilizer (Amersham/Searle) at  $60^\circ\text{C}$  for 2 h in closed vials. After cooling, 0.5 ml of NCS tissue solubilizer and 10 ml of scintillator containing 0.01% 1,4-bis-(5-phenyloxazol-2-yl) benzene and 0.4% 2,5-diphenyloxazole in toluene was added to the digested gel and radioactivity estimated in a Packard Tri-Carb scintillation spectrometer model 2650. Quenching corrections were made by means of automatic external standard and correlation curves for combined  $^{14}\text{C}$  and  $^3\text{H}$ . a, Ratio of  $^{14}\text{C}/^3\text{H}$  in each slice of gel; b, difference between observed  $^{14}\text{C}$  radioactivity in each slice and that expected if each slice had the average ratio of  $^{14}\text{C}/^3\text{H}$  (ref. 6).

mitochondria of intestinal cells has received little attention. Vitamin  $\text{D}_3$  administered *in vitro* and *in vivo* seems to alter the ability of kidney mitochondria to retain calcium *in vitro*<sup>13,14</sup> and some authors report that CaBP can influence the release of calcium from intestinal mitochondria<sup>11</sup>. In addition, a small yet direct effect of  $1,25\text{-(OH)}_2\text{D}_3$  on calcium uptake by intestinal mitochondria *in vitro* has been demonstrated<sup>15</sup>. In this experiment it was suggested that the direct effect might be of only secondary importance—the steroid caused a much greater increase in calcium uptake merely by increasing cytoplasmic concentrations of calcium. Such an effect would account for the

**Fig. 3** Time course of events occurring in the rachitic chick intestine after a single intracardial injection of  $1,25\text{-(OH)}_2\text{D}_3$  (125 ng).  $\circ$ , Synthesis of mitochondrial protein;  $\blacksquare$ , synthesis of brush border protein<sup>4</sup>;  $\bullet$ , calcium transport *in vitro*<sup>3</sup>;  $\blacktriangle$ , synthesis of CaBP (ref. 3).

transient accumulation of calcium by intestinal mitochondria *in vivo* after administration of vitamin D<sub>3</sub> (ref. 16).

We have been unable to find any role for this novel mitochondrial protein in calcium transport. Although the protein may be required to regulate some aspect of mitochondrial calcium transport, most studies have suggested that these processes are controlled both by the electrochemical gradient which is established across the inner mitochondrial membrane and by a calcium carrier, associated with the inner membrane, which catalyses a continuous efflux of calcium (for a review see ref. 17). The outer mitochondrial membrane is considered to be of little importance in calcium transport. However, the evidence for CaBP stimulation of calcium release from mitochondria<sup>11</sup> suggests an intermediary role for the mitochondrial protein in this process. Alternatively it may act independently of CaBP and sequester calcium from the mitochondrial intramembrane space thus facilitating calcium efflux and calcium transport across the intestinal cell. We do not know whether the protein is produced *de novo* or merely at a greater rate after *in vivo* administration of 1,25-(OH)<sub>2</sub>D<sub>3</sub>. Further experiments are required to answer these questions.

**Fig. 4** Distribution of newly synthesized protein between sub-mitochondrial fractions. Mitochondria from the jejuna of vitamin D-deficient chicks ([4,5-<sup>3</sup>H]leucine-labelled) or from such chicks dosed 4 h before death with 125 ng 1,25-(OH)<sub>2</sub>D<sub>3</sub> ([U-<sup>14</sup>C]leucine-labelled) as described in Fig. 1 legend were mixed 2:1 dosed: deficient (by weight) and sub-mitochondrial particles were prepared essentially by the method of Sottocasa *et al.*<sup>7</sup>. The mixture of mitochondria (20 mg protein ml<sup>-1</sup>) was resuspended in 7.5 ml 10 mM Tris-phosphate pH 7.4 at 20 °C, left on ice for 10 min and mixed with 2.5 ml 1.8 M sucrose, 2 mM (Na)<sub>2</sub>ATP, 2 mM MgSO<sub>4</sub> followed by a further 10 min on ice. Aliquots (3.5 ml) of this final mixture were sonicated on ice for three 15-s periods, with 30-s rests between each sonication, using a 9.5-mm diameter probe at an amplitude of 4 μm in a MSE ultrasonic disintegrator Mk 2. The sonicated mitochondria were then pooled and layered onto 8.5 ml 0.76 M sucrose, 5 mM Tris-phosphate pH 7.4, which was itself layered on 14 ml 1.32 M sucrose, 5 mM Tris-phosphate pH 7.4 in a Beckman SW 27 tube. After centrifugation for 3 h at 24,000 r.p.m. and 4 °C in a Beckman SW 27 rotor three fractions were collected—the pellet, designated the inner mitochondrial membrane fraction (I); material at the interface of the 0.76M and 1.32M sucrose, designated outer mitochondrial membrane fraction (O); and the top layer, designated soluble proteins (S). Portions of each fraction were assayed for: *a*, the presence of rotenone-insensitive NADH-cytochrome *c* reductase<sup>7</sup> or *b*, the percentage of total <sup>14</sup>C-labelled protein synthesis present in the peak at MW 39,000–42,000 following SDS-gel electrophoresis and a difference plot (see Figs 1, 2).

## Role of *src* gene in growth regulation of Rous sarcoma virus-infected chicken embryo fibroblasts

Gordon Parry, James C. Bartholomew & Mina J. Bissell\*

Laboratory of Chemical Biodynamics, Lawrence Berkeley Laboratory, University of California, Berkeley, California 94720

We report here a study of the mechanisms leading to loss of growth control in chicken embryo fibroblasts transformed by Rous sarcoma virus (RSV). We have been particularly concerned with the role of the *src* gene in this process, and have used RSV mutants temperature sensitive (*ts*) for transformation to investigate the nature of the growth regulatory lesion. The two principal findings were (1) the stationary phase of the cell cycle (*G*<sub>1</sub>) in chick embryo fibroblasts seems to have two distinct regulatory compartments (using the terminology of Brooks *et al.*<sup>1</sup> we refer to these as 'Q' and 'A' states). When rendered stationary at 41.5 °C by serum deprivation, normal cells enter a Q state, but cells infected with the *ts*-mutant occupy an A state. (2) Whereas normal cells can occupy either state depending on culture conditions, the *ts*-infected cells, at 41.5 °C, do not seem to enter Q even though a known *src* gene product, a kinase, is reported to be inactive at this temperature<sup>2,3</sup>. We discuss the possibility that viral factors other than the active *src* protein kinase influence growth control in infected cultures.

The experiments involved plating cultures at high density and low serum content in 35-mm plates in medium containing 0.5% chicken serum (see Fig. 1 legend), and maintaining them at either 41.5 or 35 °C for 36–48 h before starting an experiment. DNA synthesis was followed by staining cells with propidium iodide and analysing cellular fluorescence by flow cytometry. After 48 h in 0.5% serum, cells infected with the *ts* mutants LA24, LA29 or NY68 mainly occupied the *G*<sub>1</sub> compartment if cultured at 41.5 °C. However, a significant proportion was found in S if cultures were maintained at 35 °C (Table 1). Cultures maintained at 41.5 °C and then shifted to 35 °C were found to enter S approximately 8 h after shift (Fig. 1). These data confirm the early work of Bell *et al.*<sup>4</sup>. The lag period before entry into S was distinctly longer when normal cells seeded at high density

**Table 1** Growth regulation in ts-mutants LA29 and LA24 (Prague A) and NY68 (Schmidt Rupp A)

|              | Fraction of the population in cell cycle phase |       |                     |
|--------------|--|-------|---------------------|
|              | G <sub>1</sub>                                 | S     | G <sub>2</sub> + M* |
| 41.5 °C      |  |       |                     |
| Normal cells | 0.694  | 0.027 | 0.279               |
| NY 68        | 0.688  | 0.028 | 0.304               |
| LA 29        | 0.688  | 0.042 | 0.271               |
| LA 24        | 0.688  | 0.028 | 0.304               |
| 35 °C        |  |       |                     |
| Normal cells | 0.703  | 0.012 | 0.286               |
| NY 68        | 0.423  | 0.324 | 0.253               |
| LA 29        | 0.407  | 0.478 | 0.114               |
| LA 24        | 0.498  | 0.424 | 0.078               |

Chicken embryo fibroblasts were cultured as described in Fig. 1 legend except that 4 h after plating, some cultures were shifted to 35 °C whereas others were maintained at 41.5 °C. Cultures were kept at these temperatures for 48 h and the distribution of cells throughout the cycle analysed after this time period, using the procedures described in Fig. 1 legend. The cells in the G<sub>2</sub> + M category include some G<sub>1</sub> doublets which were not dissociated in our experimental conditions and thus the values in this category do not reflect true G<sub>2</sub> + M estimations.

\* Doublet population significant.

and maintained in low serum were stimulated to initiate DNA synthesis by serum addition at 41.5 °C. In six separate experiments, normal cells at 41.5 °C were found to enter S phase 12–14 h after stimulation, but surprisingly, LA24-infected cells entered S phase only 6–8 h after stimulation (Fig. 2). These results implied that in the stationary state normal and LA24-infected cultures were at different stages of the G<sub>1</sub> phase.

If normal cells were initially plated at a lower density or serum stimulated 24 h after plating instead of 48 h, then their lag period before entry into S approached that of LA24-infected cultures (Fig. 3). This clearly demonstrated that there are two

**Fig. 1** Kinetics of entry of chicken embryo fibroblasts into S phase after shift from 41.5 to 35 °C. Tertiary cells were plated in medium 199 supplemented with 2% tryptose broth, 0.5% chicken serum and 0.1% glucose, at a density of  $2 \times 10^6$  per 35-mm plate. They were kept at 41.5 °C for 36–38 h and either maintained at this temperature for a further 18 h or shifted to 35 °C. At given times, plates were removed and the cells collected and stained with propidium iodide as described elsewhere<sup>11</sup>. The stained cells were subsequently analysed in a flow cytometer and histograms of the distribution of cells throughout the cell cycle obtained. The proportion of cells in S was determined using a fitting procedure, and data analysed using a program described elsewhere<sup>12</sup>. ○, LA24-infected cells cultured at 41.5 °C and shifted to 35 °C; △, normal cells cultured at 41.5 °C and shifted to 35 °C; □, LA24-infected cells cultured at 41.5 °C and held at that temperature, and ▲, normal cells cultured at 41.5 °C and held at that temperature.

**Fig. 2** Serum stimulation of DNA synthesis in normal and LA24-infected cells maintained at 41.5 °C. Cells were seeded at  $2.0$ – $2.5 \times 10^6$  per 35-mm dish, cultures as in Fig. 1 and maintained at 41.5 °C for 48 h. DNA synthesis was initiated by the addition of 200 µl of calf serum to the cultures (no medium change: 2 ml medium per plate) and the proportion of cells in S at times after addition was determined as described in Fig. 1 legend. ○, LA24-infected cells; ■, normal cells (N).

compartments in the stationary phase of the chick embryo fibroblast cell cycle and that, by manipulating culture conditions, normal cells can be made to occupy either compartment. In contrast, it was not possible to force the LA24-infected cells into the compartment with a 12–14 h lag even by plating the cells at much higher densities than the normal cells or by growing them strictly at 42 °C. Thus, viral factors in the stationary ts-infected cells prevent these cells from entering the state which would necessitate the longer lag period. Experiments with cells infected with transformation-defective virus showed that their lag period from serum stimulation to entry into S was similar to that of normal cells (data not shown).

That chicken embryo fibroblasts apparently have two distinct stationary states within the G<sub>1</sub> phase is consistent with the recent work of Brooks *et al.*<sup>1</sup>, who discuss the evidence for two stationary states (Q and A) in mammalian cell-cycle models. Our data suggest that this is also true for the avian cell cycle, the Q state being a long-lag compartment and the A state the short-lag compartment.

Our data also indicate that virally coded factor(s) active at the non-permissive temperature must be responsible for maintaining the infected cells in the short-lag stationary stage in G<sub>1</sub> or preventing the cells from moving into the long-lag compartment. At present, the only known activity coded for by the *src* gene is a protein kinase, pp60<sup>src</sup>, which has been shown to be temperature sensitive in ts-mutants<sup>3</sup>. It is possible to argue that a low level of kinase is expressed at 41.5 °C and that this is sufficient to advance the cells further along the cycle. Such levels, however, would have to be very small in LA24-infected cells because the *in vivo* (cellular) activity of the kinase has been shown to be similar to that in uninfected controls even at 41 °C. Furthermore, in experiments carried out with cells cultured at strictly 42 °C, when such 'leakiness' would be minimized, the same differences in cycle position were observed. Also, note that in earlier studies which examined the expression of many transformation parameters at permissive and non-permissive temperatures using LA24, we failed to detect leakiness of other usual transformation parameters at the non-permissive temperature<sup>6,7</sup>.

A more feasible alternative is that an activity other than the kinase is responsible for these observations—this could be another activity associated with pp60<sup>src</sup> at the non-permissive temperature or a different protein coded for by a different reading frame of the *src* gene. Support for this suggestion comes from the observation in neuroretinal cells that the growth-regulating activity of *src* and its other transformation-related

**Fig. 3** Stimulation of DNA synthesis in normal and LA24-infected cells maintained at lower density at 41.5 °C. Cells were seeded at  $1.2 \times 10^6$  per 35-mm plate in the conditions described in Fig. 1 legend. They were kept at 41.5 °C for 18–24 h. DNA synthesis was initiated by changing the medium with fresh medium containing 2–5% chick or calf serum. Proportion of cells in S was determined as described in Fig. 1 legend. Closed symbols, control cultures; open symbols, serum-stimulated cultures.

functions may be dissociable<sup>8</sup>. Calothy *et al.*<sup>8</sup> have isolated an RSV mutant, PA-101, which is defective for 'transformation', but causes proliferation of neuroretinal cells. The 60,000 molecular weight (60K) *src* protein produced by these cells is inactive as a kinase in the immune complex assay (J. M. Bishop, personal communication).

Other observations on cells infected with temperature-sensitive RSV mutants are interesting in terms of these results. Poste and Flood<sup>9</sup> found that infected cells formed tumours at both 41 and 35 °C when grown on chicken chorioallantoic membranes. Harley and Goldfine<sup>10</sup> found that in contrast to several types of normal cells, infected cells need not synthesize lipids before initiating DNA synthesis when shifted from 41 to 35 °C. Finally, it was found that infected cells cultured at 41 °C were more sensitive to tumour promoters than were normal cells<sup>7</sup>. Data reported here, together with these observations, are consistent with the idea that cells infected with temperature-sensitive RSV mutants are in an initiated or committed state at the non-permissive temperature, and provide strong evidence for the multi-stage model of viral oncogenesis which has been discussed in detail elsewhere<sup>7</sup>.

## An embryo protein induced by SV40 virus transformation of mouse cells

Peter T. Mora, K. Chandrasekaran  
& Vivian W. McFarland

National Institutes of Health, National Cancer Institute, Bethesda, Maryland 20205

A specific protein of molecular weight (MW) ~55,000 (55K) was found recently by immunoprecipitation in all SV40 virus-transformed mammalian cells<sup>1–8</sup>, in addition to the SV40 large T antigen (~94K) and small t antigen (~17K), which are the only proteins coded by the 'early half' of the SV40 genome. The 55K protein is encoded by cellular DNA; its peptide pattern is different from that of the SV40 antigens and it is species specific in mouse, rat, hamster, monkey and human SV40-transformed (or infected) cells<sup>6–9</sup>. A 55K protein with a similar peptide pattern was found in mouse embryonal carcinoma cells not exposed to SV40<sup>4,5</sup>. Similar proteins were reported in mouse sarcomas and leukaemias induced by a great variety of aetiological agents and also in a spontaneously transformed mouse fibroblast cell line<sup>10</sup>, and it has been suggested that the protein may be a general correlate of cellular tumorigenicity<sup>11–13</sup>. We now report that the ~55K protein is present in primary cell cultures from 12–14-day old mouse embryos, but not in 16-day old mouse embryos. The embryo protein has a peptide pattern virtually indistinguishable from that of the SV40-induced protein. We also show by comparing closely related cell families that spontaneously transformed highly tumorigenic mouse cells do not possess the 55K protein.

The large T antigen, the ~55K cellular protein and the small t antigen were the major labelled proteins specifically immunoprecipitated from an SV40-transformed cloned mouse fibroblast cell \*215CSC with the SV40 tumour (T) serum<sup>1–9</sup>, as shown in the left half of the panels of Fig. 1. In the right half of Fig. 1a, the 'parent' clone 210C, not transformed by SV40, does not show these specifically immunoprecipitable proteins, and thus also lacks the 55K protein<sup>1</sup>. The T serum used is able to precipitate the cellular 55K protein independently of the presence of SV40 large T antigen, as shown on the embryonal carcinoma cell line F9 (right half of Fig. 1b)<sup>4,5,14</sup>.

Mouse embryos at various post-implantation stages were investigated and compared. Primary cultures from 12-day old mouse embryos showed the presence of specifically immunoprecipitable ~55K protein (see dark arrow in the right half of Fig. 1c). Similarly, 10–14-day mouse embryo primary cultures also possessed the 55K protein (data not shown). Equally or more highly radioactive immunoprecipitates from primary cultures from 16-day old mouse embryos exhibited no specific immunoprecipitable protein in the 55K region (right half of Fig. 1d). Apparently, beyond a certain embryonic developmental stage, significant amounts of the protein are no longer synthesized in primary cultures. When the primary embryo cultures from 12-, 14- or 17-day embryos were replated and labelled, none of the secondary or subsequent passages tested showed detectable significant amounts of 55K protein (data not shown; see also data on 210C and other established mouse and other embryo cell lines<sup>1–8</sup>). Thus, the cells which synthesize detectable 55K cellular protein in primary culture either are no longer present in further cultures in sufficient amounts or do not synthesize the 55K protein in significant amounts. In preliminary experiments with M. Dziadek we have now detected the 55K protein in 13-day mouse embryo organ cultures of liver, brain and carcass, but not in similar 16-day old embryo organ cultures, indicating that the protein indeed correlates with stages

**Fig. 1** Detection of the 55K protein in various cells. Preconfluent, exponentially growing cells in tissue culture<sup>21</sup> were labelled for 3 h with L-[<sup>35</sup>S]methionine, extracted, immunoprecipitated with either serum from hamster bearing SV40-induced tumour (T serum) or with normal (N) preimmune hamster serum, and subjected to SDS-polyacrylamide gel electrophoresis and fluorography, as described elsewhere<sup>1</sup>. Left to right, pairwise: panel a, the SV40-transformed clonal mouse embryo cell line \*215CSC and the parent clone 210C; panel b, \*215CSC and F9 teratocarcinoma cells; panel c, \*215CSC and 12-day old AL/N mouse embryo primary culture; panel d, \*215CSC and 16-day old embryo primary (see Table 1 legend for the abbreviations used for the cells). Dark wide arrows indicate the ~55K cellular protein, the open arrows the position of the SV40 large T and small t antigens, and the narrow arrows the top and bottom of the separating gels. Lines on the side of the panels show the positions of the MW marker proteins: Phosphorylase a, 94K; bovine serum albumin, 66.5K; ovalbumin, 45K; DNase I, 31K; trypsinogen, 24K; lactoglobulin, 18K. Embryo cells were obtained as follows. A virgin 8-week old AL/N female was placed in a cage with one 8-week old AL/N male mouse; 16 h later the female was checked for vaginal plug and removed from the cage. This day was designated day 0. After various (10–17) days of pregnancy, the females were killed, the uterus excised and individual embryos (average seven or eight per mouse) removed in sterile conditions. Embryos were dissected free of extraembryonic membranes, combined, minced, washed with phosphate-buffered saline pH 7.4, gently trypsinized and plated for primary cultures, as described elsewhere<sup>21</sup>. In a procedure similar to that used for all the other cells after one change of growth medium, preconfluent exponentially growing cells of the primary cultures were labelled as above. Equal volumes of the cell extract supernatants were immunoprecipitated with T or N serum, as described previously<sup>1</sup>. The input radioactivities of the T serum precipitates were 30–40% higher than the N serum precipitates, resulting in the more intense protein bands in the former. Overexposed fluorograms (7 days) are presented to facilitate detection of any (possible) 55K proteins in the N serum precipitates.

of embryogenesis and that its synthesis in the appropriate primary cultures is not a result of culture artefacts (for example, cell 'stimulation' or selection).

To obtain enough labelled 55K embryo protein for a proteolytic peptide comparison, it was necessary to have at least three synchronously pregnant AL/N mice and combine 12-day old embryos for primary culture. The 55K band, separated on an SDS-polyacrylamide gel as in Fig. 1, was cut out and eluted from the gel. A similar amount of labelled SV40-induced protein was obtained from \*215CSC cells. The two labelled proteins were subjected separately to limited proteolysis with increasing amounts of *Staphylococcus aureus* V8 protease and re-electrophoresed<sup>15</sup>. Figure 2 shows seven to nine methionine-labelled peptides with identical mobilities, appearing symmetrically with increased enzyme concentrations, from the

SV40-transformed \*215CSC cells (left half) and the 12-day old embryo primary cells (right half of fluorogram). Thus, the 55K protein in 12-day old embryos is very similar (or identical) to the SV40-induced (or stabilized) 55K cellular protein. Preliminary findings with D. Simmons also show very similar (or identical) two-dimensional electrophoresis and chromatography patterns<sup>8</sup> for the methionine-labelled tryptic peptides of the two proteins. Comparison of the proteins from SV40-transformed cells from different species suggests that the protein is an evolutionarily conserved protein<sup>8</sup>, and might thus have an essential cellular function. The results indicate that the host gene(s) for such protein(s) is functioning constitutively in the embryo during a certain phase of embryogenesis. In established embryo cells

**Fig. 2** Comparison of peptides obtained by partial proteolysis of the isolated 55K proteins from 12-day old embryo primary cells and from the SV40-transformed \*215CSC cells. Twenty 12-day old AL/N embryos were used for primary cultures and labelled as in Fig. 1. The \*215CSC cells were also labelled similarly. Immunoprecipitates with T serum were separated as in Fig. 1. The 55K protein bands were located, cut out, homogenized in a buffer containing 10 mM NaHCO<sub>3</sub>, 0.1% SDS, 0.1%  $\beta$ -mercaptoethanol and 20% sucrose<sup>15</sup>, and extracted at 37 °C overnight. The extraction mixture was centrifuged and the supernatant sampled for counting. The total radioactivities recovered were 35,889 c.p.m. from the embryo cells and 23,940 c.p.m. from the \*215CSC cells. Four aliquots (20  $\mu$ l) each of the two supernatants, containing 8,545 c.p.m. (embryo) and 5,700 c.p.m. (\*215CSC), were placed in wells in the 3% spacing gel. Homogenizing buffer<sup>1</sup> (10  $\mu$ l) containing 0, 45, 90 and 450 ng of *Staphylococcus aureus* V8 protease (Miles) was placed in the wells as shown on the top of the figure. The wells were filled with a sample electrophoresis buffer<sup>22</sup>, subjected to electrophoresis (30 V, 3 h) until the marker dye had penetrated 1 inch of the stacking gel. Electrophoresis continued at 140 V for 2 h, until the dye reached the bottom of the gel. The gel was stained, destained and fluorographed as before<sup>1</sup>. Exposure was for 20 days. The solid arrow points to the undigested 55K protein present in largest amount in the gel columns from the buffer controls.

**Table 1** Absence of correlation between tumorigenicity and the 55K protein

| Cell     | TD <sub>50</sub> | 55K protein | Cell     | TD <sub>50</sub> | 55K protein |
|----------|------------------|-------------|----------|------------------|-------------|
| 104C     | 2                | —           | *215CSC  | 6.4              | +           |
| *106CSC  | 4                | +           | *221CSCT | 2                | +           |

| *214CSC  | >6               | +           | *314TSCT | >5               | +           |
|          |                  |             | *315TSCT | 5                | +           |

Properties of mouse embryo cell lines from three cell 'families'. The relation and generation of the cells are indicated with the postfix letters in sequence: C denotes a clone (obtained by a single-cell technique<sup>20</sup>); S, SV40 transformed; C, recloned; T, tumour cell line obtained from the clone immediately above (by injecting 10<sup>5</sup>–10<sup>7</sup> cells into a syngeneic mouse and re-establishing a cell line from the tumour<sup>19</sup>). An asterisk before the number denotes that the cell is SV40 T-antigen positive. The cells in the 100 and 200 families were from AL/N strain mouse embryo<sup>19</sup>; those in the 300 family were from BALB/c mouse embryo. The TD<sub>50</sub> denotes tumorigenicity, determined by intramuscular inoculation of 10-fold cell dilutions (minimum of three each) into batches of 6–8-week old syngeneic mice (10 mice per batch): TD<sub>50</sub> = log<sub>10</sub>[number of cells producing rapidly lethal sarcomas in 50% of the mice inoculated]; observed and calculated as in ref. 19. The presence (+) or absence (—) of the 55K protein was determined as in Fig. 1. The SV40 T antiserum used (lot 78 × 222, NCI) was capable of precipitating the 55K protein alone, when such protein was separated by gel electrophoresis from the SV40 T antigen and eluted separately (as in Fig. 2) and reprecipitated (not shown) (see also the precipitation of the F9 and embryo cells in Fig. 1). Also, when the T-antigen-negative labelled cell extracts were mixed with excess of T-antigen-positive unlabelled cell extracts no more immunoprecipitable radioactive counts were seen in the 55K region than without mixing (data not shown). Some of the cells had been characterized previously for biochemical, tissue culture and *in vivo* growth properties<sup>19,20</sup>.

(including many clones<sup>1</sup>), the genes are present, but the proteins are not induced and/or not 'stabilized', unless the cells are infected by SV40.

To determine whether or not the 55K protein is a general correlate of cellular tumorigenicity, the presence of the 55K protein in three families of established mouse fibroblast cells were compared with tumorigenicity in the syngeneic mouse. There was no correlation at all in the mouse embryo fibroblast cells tested (Table 1). The highly malignant sarcomagenic cells in all three families from two strains (AL/N and BALB/c) of mice, which became tumorigenic by spontaneous transformation (cells 104C, 124CSCT, 127CSCT, 128CSCT, 219CT and 301T), did not possess detectable amounts of 55K protein when tested with the SV40 T antiserum, whereas the correlation was found without exception in all three families with the cells expressing SV40 T antigen and the 55K protein<sup>1</sup>. Tumour cell lines 124, 127 and 128CSCT and the 134CSCTC clone carry late SV40 DNA, but are revertant in the sense that they do not possess the SV40 early gene<sup>16</sup>. This shows that the continued presence of at least one copy<sup>16</sup> of the SV40 early gene (as in \*106CSC) and its protein product (T antigen) is sufficient and, in established cell lines, necessary not only for the initiation<sup>5</sup> but also for the maintenance of the induction (and/or stabilization—possibly through interaction with the T antigen<sup>17</sup>) of the 55K protein.

The identification of the SV40-induced mouse cellular 55K protein as an embryo protein (and by implication and analogy to similar proteins synthesized by cells of other mammals transformed by other means<sup>6–11,13</sup>) has opened up new molecular approaches for developmental biology. For example, it was recently shown that the methionine-labelled peptides are very similar when the cells are transformed by SV40 or by the related BK and JC viruses in the same species (hamster), or when the cells of related species (monkey and human) are infected lytically or transformed by SV40<sup>9</sup>. Our work now leads us to expect that all these proteins will be found to be the corresponding embryo proteins in the various species. Immunological cross-reactivities between the surface of SV40-transformed and fetal hamster cells have been reported<sup>18</sup>.

We thank Mr Lorenzo Waters for assistance, Dr S. W. Luborsky for discussion, and Drs D. Simmons and M. Dziadek for allowing us to quote results.

We have identified a group of 8 (among 39) human tumour cell strains deficient in the ability to support the growth of adenovirus 5 preparations treated with *N*-methyl-*N*'-nitro-*N*-nitrosoguanidine (MNNG), but able to support the growth of non-treated adenovirus normally<sup>1,2</sup>. This deficient behaviour defines the Mer<sup>−</sup> phenotype<sup>3</sup>. Strains having the Mer<sup>−</sup> phenotype were found to arise from tumours originating in four different organs. Relative to Mer<sup>+</sup> strains, Mer<sup>−</sup> tumour strains showed greater sensitivity to MNNG-produced killing, greater MNNG-stimulated 'DNA repair' synthesis and a more rapid MNNG-produced decrease in semi-conservative DNA synthesis<sup>2</sup>. Here we report that (1) Mer<sup>−</sup> strains are deficient in removing O<sup>6</sup>-methylguanine (O<sup>6</sup>-MeG) from their DNA after [*Me*-<sup>14</sup>C]MNNG treatment (Table 1); (2) Mer<sup>−</sup> tumour strains originate from tumours arising in patients having Mer<sup>+</sup> normal fibroblasts (Fig. 1a, b); (3) SV40 transformation of (Mer<sup>+</sup>) human fibroblasts often converts them to Mer<sup>−</sup> strains (Fig. 1c, d); (4) MNNG produces more sister chromatid exchanges (SCEs) in Mer<sup>−</sup> than in Mer<sup>+</sup> cell strains (Fig. 2).

Mer<sup>+</sup> and Mer<sup>−</sup> strains were treated with <sup>14</sup>C-MNNG and analysed directly following and 20-h after treatment for DNA-bound O<sup>6</sup>-MeG and *N*<sup>7</sup>-MeG (*N*<sup>7</sup>-methylguanine; see Table 1). O<sup>6</sup>-MeG is not removed appreciably from the DNA of Mer<sup>−</sup> strains over the 20-h incubation period. However, the amount of O<sup>6</sup>-MeG (relative to *N*<sup>7</sup>-MeG) found in the DNA of MNNG-treated Mer<sup>+</sup> strains shortly after MNNG treatment is about

threefold less than that found in Mer<sup>-</sup> strains, presumably reflecting active removal by Mer<sup>+</sup> strains of O<sup>6</sup>-MeG during the 1-h MNNG treatment (ref. 3 and B. Strauss, personal communication). During the 20-h incubation after MNNG treatment, the Mer<sup>+</sup> strains continued to remove O<sup>6</sup>-MeG from their DNA. By contrast, in the Mer<sup>-</sup> strains, the O<sup>6</sup>-MeG/N<sup>7</sup>-MeG ratio increased, presumably reflecting the slow loss of N<sup>7</sup>-MeG from the DNA expected at 37°C (refs 3-6). (Our data are consistent with a half life for DNA-bound N<sup>7</sup>-MeG of ~46 h, which is in the range of those published<sup>5,6</sup>.)

We questioned whether the tumours that gave rise to the Mer<sup>-</sup> tumour strains arose in persons who were entirely composed of Mer<sup>-</sup> cells (indicating possible genetic inheritance of the condition) or whether the non-tumour cells of such patients would be Mer<sup>+</sup> (indicating that the Mer<sup>-</sup> condition may be a property of only tumour cells). To investigate this question experimentally, we obtained strains of normal fibroblasts prepared from two patients whose tumours had given rise to the Mer<sup>-</sup> A427N and Hs750T strains. The normally appearing fibroblast strains, A427F and Hs750M, were both found to be Mer<sup>+</sup> (Fig. 1a). Studies of post-MNNG colony-forming ability (Fig. 1b) established that the fibroblast lines A427F and Hs750M had sensitivities to MNNG similar to those of human fibroblasts (see refs 2, 7, and Fig. 1d). The A427N tumour line, however, showed the increased sensitivity to MNNG-produced

**Fig. 1** a, b, MNNG-produced inactivation of adenovirus 5 (a) and of colony-forming ability (b) using normal or tumour cell strains from the same patient. Patient 1: ○, A427F (normal fibroblast strain) and ●, A427N (lung tumour strain). Patient 2: △, Hs750M (normal fibroblast strain) and ▲, Hs750T (stomach tumour strain). For a, adenovirus 5 was inactivated with MNNG and subsequently assayed for plaque-forming ability using monolayers of the above strains as described<sup>19</sup>. For colony-forming ability (b), cells were seeded at low density, treated with MNNG and grown to colonies as described elsewhere<sup>7</sup>. No colony data are presented for Hs750T because it did not form colonies. Virus plaquing efficiencies and cellular colony-forming efficiencies were in the ranges of those reported previously and were not correlated with the sensitivities observed. c, d, MNNG-produced inactivation of adenovirus 5 (c) and of colony-forming ability (d) using normal human fibroblasts, SV40-transformed fibroblasts and Mer<sup>-</sup> tumour strains. The cell strains used were: ○, AT5BIVA2; △, WI38; ▲, WI38VA13; ◆, GM54; ■, GM638; ○, IMR90; ● and ●, IMR90-830; ●, IMR90-890; □, WI26; ■, WI26VA4; ▲, GM637; ▼, XP12; ▼, W98VA1; ◆, SV80; ▼, WI8VA2; ■, A172; ◆, A875; ◆, BE.

**Fig. 2** Number of MNNG-induced SCEs as a function of MNNG concentration used to treat cells of five Mer<sup>-</sup> and seven Mer<sup>+</sup> strains. Confluent cells were split into 75-cm<sup>2</sup> flasks containing DMEM or McCoy's 5A plus 10% fetal calf serum. The next morning, stocks of MNNG were diluted into the medium to obtain the desired concentrations. Bromodeoxyuridine was added to 10 μg ml<sup>-1</sup>. After 57-80 h of incubation, colcemid (10 μg ml<sup>-1</sup>, Gibco) was added to 0.1-0.2 μg ml<sup>-1</sup>. After 4 h further incubation, the cells were collected, centrifuged and resuspended in 5 ml 0.04-0.075 M KCl, centrifuged and fixed in 5 ml methanol/glacial acetic acid, 3:1, and dried on to slides. For differential staining, slides were either immersed in 4'-6-diamidino-2-phenylindole at 10 μg ml<sup>-1</sup> of distilled water for at least 3 min, removed and treated with three drops 0.2 M NaPO<sub>4</sub> buffer, pH 11.5, or stained by a modified Hoechst 33258-Giemsa technique<sup>20,21</sup>. The chromosomes of at least 15 metaphase cells were counted to determine each point. Standard deviations were typically 0.2-0.3 of the average. The cell strains used, followed by the zero dose level of SCEs per chromosome, were: Mer<sup>-</sup>: ●, A1336 (0.34); ●, A2095 (0.14); ▼, A1235 (0.18); ▲, WI38VA13 (0.38); △, A253 (0.26); Mer<sup>+</sup>: □, A388 (0.35); ○, IMR90 (0.16); ■, A549 (0.15); ●, A673 (0.14); ▲, A704 (0.20); ▼, HuTu80 (0.16); and ▼, W98VA1 (0.64).

killing characteristic of Mer<sup>-</sup> tumour strains (ref. 2 and Fig. 1d); tumour strain Hs750T did not form colonies. Therefore, the respective patients were not entirely composed of Mer<sup>-</sup> cells, showing that generalized inheritance of the Mer<sup>-</sup> condition did not occur.

SV40-transformed human fibroblast strains were tested for their Mer phenotype to determine whether the Mer<sup>-</sup> phenotype was characteristic only of certain strains derived from human tumours, or if human strains transformed by other means were also Mer<sup>-</sup>. Of 11 SV40-transformed strains, 7 were found to be Mer<sup>-</sup> and 4 Mer<sup>+</sup> (Fig. 1c Table 1). The available non-transformed human fibroblast 'parents' of these transformed strains (Table 2) were all Mer<sup>+</sup>, including three strains (IMR90, WI38 and GM54) that gave rise to Mer<sup>-</sup> transformed strains (Table 2). The result indicates that SV40 transformation often converts Mer<sup>+</sup> strains to Mer<sup>-</sup> strains, or selects Mer<sup>-</sup> variants as targets for transformation.

The SV40-produced Mer<sup>-</sup> strains were not as sensitive as Mer<sup>-</sup> tumour strains to the killing effects of MNNG (Fig. 1d), suggesting that either the Mer<sup>-</sup> tumour strains are defective in the ability to remove an additional MNNG-produced lesion, or that the cellular response of the two groups of Mer<sup>-</sup> strains to O<sup>6</sup>-MeG differs. Further, although the SV40-produced Mer<sup>-</sup> cells were more MNNG sensitive than their parent fibroblasts, they were not more sensitive to MNNG-produced killing than were Mer<sup>+</sup> SV40-transformed cells, and, therefore, were not killed by O<sup>6</sup>-MeG, which they are deficient in excising. (To be certain that the Mer<sup>-</sup> phenotype of the tumour strains was not caused by adventitious SV40 infection, we found, using our assay<sup>8</sup>, that SV40 T-antigen was not detectable in any of the eight Mer<sup>-</sup> tumour strains described above. By contrast, and as a control, more than 95% of the nuclei of the SV80 strain contained T-antigen.)

Sister chromatid exchanges<sup>9,10</sup> reflect cellular DNA damage due to various mutagenic and carcinogenic agents<sup>10,11</sup> and are increased in damaged cells lacking certain DNA repair processes<sup>12,13</sup>. Figure 2 shows that Mer<sup>-</sup> strains, including one (WI38VA13) derived from normal fibroblasts (WI38), gave rise to detectable levels of SCEs at much (up to 250-fold) lower concentrations of MNNG than did Mer<sup>+</sup> strains. However, there

tibility to MNNG-produced SCEs in addition to the differences noted in our introduction. Further, the demonstration of the Mer<sup>-</sup> behaviour of the HeLa S3 and XP12 strains, known to be more mutable by alkylating agents than either the HeLa CCL2 or the GM637 strain<sup>14,15</sup>, provides a link between the Mer<sup>-</sup> phenotype and increased sensitivity to mutagenesis by alkylating agents.

The two SV40-transformed human strains, identified here as Mer<sup>-</sup> (XP12, derived from a xeroderma pigmentosum (XP) patient) and Mer<sup>+</sup> (GM637, derived from a control person), are divergent both in their susceptibilities to MNNG-produced SCEs (XP12 was the more sensitive<sup>12</sup>) and in their abilities to remove O<sup>6</sup>-alkylguanines from their DNA<sup>4,16</sup> (GM637 showed such excision, XP12 did not). These differences were provisionally hypothesized to be another manifestation of the repair defect in XP fibroblasts that leads to deficient repair of UV ray-damaged DNA. We believe that these differences are more probably due to the SV40-produced molecular changes that lead to the expression of the Mer<sup>-</sup> phenotype.

The identification and characterization of the Mer<sup>-</sup> phenotype in many transformed human cell lines, but not in normal human fibroblasts, leave us unable to decide whether the Mer<sup>-</sup> repair deficiency enhances (or is produced by) transformation, or whether virally produced transformation often leaves a Mer<sup>-</sup> 'footprint'. That 1-chloroethyl-1-nitrosourea (CNU) produces

more DNA cross-links in Mer<sup>-</sup> than in Mer<sup>+</sup> tumour strains (see accompanying manuscript<sup>17</sup>) further suggests that the presence or absence of the Mer repair system may be the molecular reason for the *in vivo* failure or success of chemotherapeutic regimens using agents (1,3-bis-chloroethylnitrosourea (BCNU) or 3-cyclohexyl-1-chloroethyl-1-nitrosourea (CCNU)) having modes of action similar to that of CNU.

We thank Drs Kurt Kohn, R. M. Baker and Len Erickson for helpful discussions. Dr Kohn first suggested investigating the Mer phenotype of WI38VA13 and Dr Baker provided strains HeLa CCL2, HeLa S3, GM637, and XP12 and data before publication. We also thank Dr S. A. Aaronson for the supply of human tumour cell strains, all of which begin with 'A' in this work, Dr Hermann Autrup both for providing us with N<sup>3</sup>-MeA, N<sup>7</sup>-MeG and O<sup>6</sup>-MeG standards and for encouragement, Dr Tsuyoshi Kakefuda for instruction in HPLC techniques and for his patience, and Dr Ken Kraemer for suggestions concerning the manuscript.

## DNA cross-linking and monoadduct repair in nitrosourea-treated human tumour cells

Leonard C. Erickson\*, Guy Laurent, Nancy A. Sharkey & Kurt W. Kohn

Laboratory of Molecular Pharmacology, Developmental Therapeutics Program, Division of Cancer Treatment, National Cancer Institute, National Institutes of Health, Bethesda, Maryland 20205

The 1-(2-chloroethyl)-1-nitrosoureas are potent anti-cancer drugs<sup>1,2</sup> which produce DNA inter-strand cross-links in a two-step reaction sequence. The first step was proposed to be an addition of a chloroethyl group to a guanine-O<sup>6</sup> position of DNA<sup>3</sup>; the second step, which occurs over a period of several hours in the absence of free drug<sup>3-6</sup>, could then form an inter-strand cross-link by the slow reaction of the bound chloroethyl group with a nucleophilic site on the opposite DNA strand. The delay between the formation of chloroethyl monoadducts and the formation of inter-strand cross-links allows time for a DNA repair mechanism, capable of removing the monoadducts, to prevent the cross-linking. We recently proposed this mechanism to account for a difference in inter-strand cross-linking between a normal and a transformed human cell strain<sup>6</sup>. Day and his coworkers (see refs 7, 8 and previous paper<sup>9</sup>) found that some human tumour cell strains (designated Mer<sup>-</sup> phenotype) are deficient in the ability to repair O<sup>6</sup>-methylguanine lesions in DNA. We therefore hypothesized that the repair function that removes O<sup>6</sup>-methylguanine residues from DNA would also remove chloroethyl monoadducts and hence prevent chloroethylnitrosourea-induced inter-strand cross-linking. We now present evidence that supports this hypothesis and indicates also that the O<sup>6</sup>-methylguanine repair confers resistance to cell killing by chloroethylnitrosourea.

Thirteen human cell strains, most of them derived from malignant tumours, were studied (Table 1). The phenotype of each strain was classified as Mer<sup>+</sup> or Mer<sup>-</sup> by R. Day, on the

basis of whether or not the cells were proficient in supporting the growth of adenovirus 5 treated with N-methyl-N'-nitro-N-nitrosoguanidine<sup>7-9</sup>.

The cells were treated with 1-(2-chloroethyl)-1-nitrosourea (CNU) for 1 h and then incubated for 6 h to allow inter-strand cross-links to form<sup>5,6</sup>. Inter-strand cross-linking and DNA-protein cross-linking were determined by the alkaline elution method<sup>10-12</sup>, using the same procedures as in our previous study<sup>6</sup>. The elution assay, when performed directly (without proteinase), measures the combined effect of inter-strand and DNA-protein cross-links. The major contribution to this measurement, in the case of chloroethylnitrosoureas, is from DNA-protein cross-links<sup>5,6</sup>. The assay with proteinase greatly reduces or eliminates the DNA-protein cross-links, and is assumed to be a measure of inter-strand cross-linking<sup>11</sup>.

The results show a clear correlation between inter-strand

**Fig. 1** Inter-strand cross-linking (assay with proteinase) plotted against DNA-protein cross-linking, estimated by assay without proteinase in the same experiment. Cross-link index is defined in Table 1 legend. Open symbols, Mer<sup>-</sup> strains; closed and half-closed symbols, Mer<sup>+</sup> strains. The symbols representing individual cell strains are shown in Table 1.

Cells previously labelled with [2-<sup>14</sup>C]thymidine (0.01  $\mu$ Ci ml<sup>-1</sup>, 24 h) were treated with 50 or 100  $\mu$ M CNU for 1 h in culture medium (Dulbecco's modified Eagle's medium, 10% heat-inactivated fetal calf serum, 0.02 M HEPES buffer) and then incubated for 6 h in drug-free medium. Control cells were similarly run without drug treatment. After collection,  $2-5 \times 10^5$  cells were mixed with  $5 \times 10^5$  L1210 mouse leukaemia cells whose DNA had been labelled with <sup>3</sup>H-thymidine (0.1  $\mu$ Ci ml<sup>-1</sup>, 24 h); these cells served as internal standards. The mixed cell suspensions were exposed to 300 R of <sup>137</sup>Cs  $\gamma$ -ray irradiation at 0 °C just before alkaline elution, which was carried out by the same procedures as used in our previous study<sup>6</sup>. Cells were deposited on 2- $\mu$ m-pore size polyvinyl chloride filters and lysed with 2% SDS, 0.02 M EDTA, 0.1 M glycine, pH 10, with or without 0.5 mg ml<sup>-1</sup> proteinase K. Alkaline elution was with tetrapropylammonium hydroxide/0.02 M H<sub>2</sub>EDTA, pH 12.1, pumped at a rate of 2 ml h<sup>-1</sup>. When proteinase K was used, the eluting solution also contained 0.1% SDS. When proteinase K was not used, the lysis solution was washed out with 0.04 M Na-EDTA, pH 10, before elution at pH 12.1. Cross-link index is defined as  $[(1-R_0)/(1-R_1)]^{1/2} - 1$ , where  $R_0$  and  $R_1$  are the 'relative retention' for untreated and CNU-treated cells, respectively<sup>5</sup>. Relative retention is the fraction of the <sup>14</sup>C-DNA remaining on the filter when 30% of the internal standard <sup>3</sup>H-DNA remained on the filter. The range of values obtained in independent experiments are given in parentheses; the superscript indicates the number of experiments. Symbols in the first column on the left are used to represent the cell strains in Figs 1 and 2. ca., carcinoma. Cell strains: IMR90, normal human embryo cells obtained from W. Nichols; VA13, an SV40-transformed derivative of normal human embryo strain WI38; BE, obtained from B. Giovannella; HT29, obtained from E. Jensen. The other strains were obtained from R. Day.

cross-linking (proteinase assay) and methylation repair capacity (Table 1). The six strains deficient in this capacity (Mer<sup>-</sup> phenotype) produced consistently higher inter-strand cross-linking levels than did five of the seven Mer<sup>+</sup> strains studied.

The remaining two Mer<sup>+</sup> strains (A431 and HT1080) gave deviant results. Strain A431 yielded high inter-strand cross-linking values, in the range of the Mer<sup>-</sup> strains. In view of this result, Day (personal communication) restudied the A431 culture, and found that with continued passage the culture had attained a large Mer<sup>-</sup> component. In the case of the HT1080 strain, the first two inter-strand cross-link determinations were low, well within the Mer<sup>+</sup> range, whereas the last two determinations were high, well within the Mer<sup>-</sup> range. This observation raises the question of whether cells in culture can lose the Mer<sup>+</sup> phenotype.

In addition to assays for inter-strand cross-links, most of the experiments included assays for DNA-protein cross-links. The assays for total cross-links (no proteinase), which we take to be essentially measures of DNA-protein cross-linking, showed no significant differences between the Mer<sup>+</sup> and Mer<sup>-</sup> strains (Table 1). Hence, the differences in inter-strand cross-linking cannot be attributed simply to differences in drug uptake or inactivation.

DNA-protein cross-links form without delay<sup>5,6</sup> and probably involve different sites of linking to DNA from inter-strand cross-links. If the differences in inter-strand cross-linking are principally due to differences in a specific DNA repair mechanism, DNA-protein cross-linking, apparently little affected by such repair, could be a measure of the extent of drug entry and intracellular reactivity in particular experiments. The use of DNA-protein cross-linking as a gauge of intracellular drug delivery is plausible also because chloroethylnitrosoureas are lipid soluble, and hence their entry into cells is not likely to be limited by membrane barriers.

Using this concept, the value for inter-strand cross-linking (proteinase assay) was plotted against the value for DNA-protein cross-linking (no proteinase) obtained in the same experiment (Fig. 1). The cell strains are seen to give a bimodal distribution, the Mer<sup>-</sup> strains (open symbols) being clearly separated from most of the Mer<sup>+</sup> strains (closed and half-closed symbols). The A431 (Mer<sup>+</sup>) strain again falls within the Mer<sup>-</sup> group (half closed circles). The segregation of the cell strains into two distinct groups is analogous to the distinct grouping with respect to methylation repair noted by Day and his

coworkers<sup>7-9</sup>. This lends additional support to the idea that the cells differ with respect to a discrete phenotype.

The cytotoxic sensitivity of the cell strains to CNU was determined in terms of inhibition of cell proliferation (Fig. 2). Results with this assay have been found to be consistent with colony formation assays<sup>6</sup>. The six Mer<sup>-</sup> strains (open symbols) were clearly more sensitive to CNU than were five of the seven Mer<sup>+</sup> strains.

The exceptions again were strains A431 (Fig. 2, half-closed circles) and HT1080 (Fig. 2, half-closed triangles). The A431 strain exhibited low sensitivity at low drug concentrations and high sensitivity at high concentration. It is possible that this strain has a limited capacity for O<sup>6</sup>-alkyl guanine repair, so that at low levels of DNA damage it seems to be Mer<sup>+</sup>, but at high levels seems to be Mer<sup>-</sup>.

Our results, together with those of Day and his colleagues<sup>7-9</sup>, suggest that the loss of a specific DNA repair function could simultaneously make cells susceptible to neoplastic transformation and make the resulting tumours vulnerable to

**Fig. 2** Effect of CNU treatment on proliferation of various cell strains. Cells were treated with CNU for 1 h. After drug removal, the cells were allowed to proliferate in fresh medium for 3 days (three to five doubling times for control cells). Symbols are as in Fig. 1 and Table 1.

chemotherapy with certain DNA damaging agents. The loss of the ability to repair  $O^6$ -alkyl guanine lesions in DNA could make the cells susceptible to the mutagenic effects of methylating agents and related carcinogens. Such cells would have an increased likelihood of malignant transformation, and could give rise to the  $Mer^-$  tumours. Our results suggest that such tumours may be vulnerable to DNA cross-linking by 1-(2-chloroethyl)-1-nitrosoureas.

Recent evidence indicates that repair of  $O^6$ -methylguanine and  $O^6$ -ethylguanine involves destruction rather than excision of these residues from DNA<sup>13-15</sup>. As  $O^6$ -alkylation markedly alters the bond conjugation in the guanine ring, this could be the recognition feature for an enzyme which acts on the ring regardless of the identity of the alkylating group. Thus,  $O^6$ -methylguanine and  $O^6$ -2-chloroethylguanine residues might be destroyed by the same enzyme.

We thank Dr Rufus Day for providing cell strains which he had determined to have the  $Mer^-$  or  $Mer^+$  phenotype, and for many fruitful discussions. G.L. was supported by grants from the Fogarty International Center (NIH) and the Rose and Jean Hoguet Foundation.

## Transient haem-globin interactions in photodeligated carboxyhaemoglobin and subunits

L. Lindqvist\*, S. El Mohsni\*†, F. Tfibel\* & B. Alpert†

Although the fixation of ligand to haemoglobin (Hb) is known to be accompanied by changes in protein conformation<sup>1</sup> regulating the oxygen exchange in blood, the mechanism triggering these changes remains undecided<sup>2-4</sup>. We now report a dynamic approach to this problem using results obtained in a nanosecond laser photolysis study of carboxyhaemoglobin (HbCO) and its isolated subunits. The study is based on our previous observation<sup>5</sup> of a structural evolution of free Hb after photodeligation, manifested through slight variations of the protein spectrum in the microsecond range. It is now found that the isolated subunits also show this behaviour. The duration of the spectral evolution is  $\sim 2\mu s$  for the three proteins and the activation energy of the process  $\sim 9 \text{ kcal mol}^{-1}$ . The spectral evolution is attributed to local conformation changes at the haem region, occurring during the structural relaxation of the freshly deligated protein. The results for the isolated chains show that such changes exist even in the absence of the R-T transition.

Hb and its isolated subunits were prepared from fresh human adult blood using standard procedures<sup>6,7</sup>. Aqueous solutions of the proteins at pH 7.0 (0.1 M potassium phosphate buffer) were degassed by pumping, and potassium dithionite was added to

eliminate the last traces of oxygen. The CO-complexes were obtained by exposure of these solutions to CO; dissolved excess CO was removed by rough pumping, and an atmosphere of argon was applied above the solutions. The experiments were performed at 22 °C except where otherwise stated.

Photolysis light pulses of wavelength 530 nm and pulsewidth 7 ns at half-maximum were obtained from an Nd-glass laser. Maximum energy incident in the samples was 100 mJ. Optical transmission changes in the irradiated solutions (across 1 mm) were measured as a function of time at different wavelengths<sup>5</sup>.

We previously<sup>5</sup> showed that photodeligated Hb initially has an absorption spectrum slightly different from that of stable deoxy Hb (Fig. 1a); however, this difference disappears within a few microseconds. We have established<sup>8</sup> that this behaviour is not a multiphoton effect; such effects can always be suspected in pulsed laser studies<sup>9</sup>. The existence of a microsecond evolution of photodeligated Hb has also recently been confirmed by resonance Raman spectroscopy<sup>10</sup>.

Figure 1b and c show spectra measured after 100% photodeligation of the subunit CO complexes by laser excitation. The Soret band of the  $\alpha$  chain is reduced in intensity compared with that of the stable deoxy protein, although to a smaller extent (7%) than that observed for Hb (18%). The corresponding Soret bands of the  $\beta$  chain seem to be coincident with each other. No distortion of the  $\alpha$  and  $\beta$  subunit spectra was detectable in the 500-600 nm range, in contrast with the 10 nm displacement of the 555 nm band to the red observed for Hb<sup>5</sup>.

The distortion in the spectrum of  $\alpha$  chain disappeared after a few microseconds. (When calculating the amplitude of spectral variation in this time range, correction was made for the partial (30-40%) recovery of the ligated proteins occurring during the first few hundred nanoseconds, due to geminate recombination<sup>5,8</sup>.) A microsecond spectral variation was also observed for the  $\beta$  chain, although of very low amplitude. This variation showed that the Soret band of the photodeligated  $\beta$  chain is initially depressed by  $\sim 1\%$  compared with that of the stable deoxy protein, a difference too small to appear in the transient spectrum shown in Fig. 1c.

The kinetics of the spectral evolution for the three proteins were obtained from measurements at 430 nm. Exponential decays showed that the transient form of the deligated proteins relaxes in a first-order reaction. The reactions occurring on excitation can then be written

The rate constant  $k$  is  $4.1 \times 10^5 \text{ s}^{-1}$  ( $\pm 10\%$ ) for Hb,  $6.6 \times 10^5 \text{ s}^{-1}$  ( $\pm 10\%$ ) for  $\alpha$  and  $6 \times 10^5 \text{ s}^{-1}$  ( $\pm 30\%$ ) for  $\beta$ . Activation energies ( $E_a$ ) were determined from the temperature dependence of  $k$  (13-35 °C). Figure 2 shows the results in an Arrhenius plot. A value of  $E_a = 9 \pm 1 \text{ kcal mol}^{-1}$  was obtained for Hb and  $\alpha$ . The results for the  $\beta$  chain, although only semi-quantitative, indicate that its  $E_a$  value is at least of the same order of magnitude as that of the other two proteins.

The spectral evolution (process (2)) is most probably due to changes in the haem environment occurring during structural relaxation of the proteins following photodeligation. Such a relaxation must occur in Hb because the reversible binding of ligand to this protein is known to be accompanied by a rearrangement of the four chains with respect to each other<sup>2</sup> (the quaternary change) and by tertiary conformation changes, including small readjustments of the haem-protein contacts<sup>11-13</sup>. Structural studies of the isolated chains are lacking; however, X-ray investigations of myoglobin<sup>14</sup> have shown that readjustments in the haem region occur on ligand binding to this non-cooperative protein and one may expect a similar behaviour for the isolated  $\alpha$  and  $\beta$  chains.

As the non-cooperative isolated subunits show the evolution effect, the relaxation cannot be explained by the occurrence of a

**Fig. 1** Transient absorption spectra (○) of Hb (a), α (b) and β (c) measured after pulsed laser photodissociation of the corresponding CO complexes (end-of-pulse spectra). The absorption spectra of the CO-proteins (—) and the stable deoxy proteins (---) are also shown. Haem concentration ~50 μM.

quaternary structure change. However, it is striking that the spectral variation for Hb is not the mean of those for the isolated chains but is instead appreciably enhanced. This enhancement indicates that the α and β haem regions of this cooperative protein undergo more profound changes, probably because of the quaternary structure relaxation.

Gibson discovered in his early flash-photolytic studies<sup>15</sup> the transient appearance of a spectrally distorted form of deoxy Hb with high reactivity ('quickly reacting form'). More recently, Sawicki and Gibson<sup>16</sup> reported the transient spectrum observed following laser irradiation (of 1 μs duration) of HbCO. They did not detect any similar effect with the isolated chains and therefore stressed the role of the quaternary change in the transient Hb spectrum. Apart from the shape of this latter spectrum, our results differ from those of Sawicki and Gibson. However, differences in experimental conditions (time resolution, pH) preclude a more detailed comparison.

The  $E_a$  value of the spectral evolution observed in the present study is high, considering the weakness of the interactions determining the tertiary conformation. It is, on the other hand, of the same order of magnitude as the energy of the haem-proximal histidine (F8) coordination bond (~10 kcal mol<sup>-1</sup>, as estimated from results for cobaltoporphyrins<sup>17</sup>). Also, the rate constant of process (2) is in the frequency range of the dissociation rate (10<sup>5</sup>–10<sup>6</sup> s<sup>-1</sup>) for a number of five-coordinate complexes of ferroporphyrins with nitrogenous bases<sup>18,19</sup>. It is therefore tempting to suggest that the structural change in deoxy Hb (process (2)) is controlled by the thermally activated opening of the haem-histidine (F8) coordination bond. Removal of the stress in the unrelaxed deoxy Hb may be facilitated by haem and histidine movements during the transient opening of this bond.

**Fig. 2** Temperature variation of the rate constant  $k$  associated with the spectral evolution (process (2)) of photodissociated Hb (○), α (●) and β (□) on an Arrhenius plot. The high uncertainty in the points for the β subunit are due to the extremely small spectral change observed for this protein.

## Human immunoglobulin variable region genes—DNA sequences of two V<sub>κ</sub> genes and a pseudogene

David L. Bentley & T. H. Rabbitts

MRC Laboratory of Molecular Biology, Hills Road, Cambridge CB2 2QH, UK

The study of immunoglobulin genes at the molecular level can allow us to elucidate the origin of antibody diversity. Investigations of immunoglobulin gene structure in the mouse have shown that light chains are encoded by three gene segments: the C gene encoding the constant region and the V and J genes encoding the variable region. In antibody-producing cells the V and J genes join together to create a complete immunoglobulin gene<sup>1,2</sup>. No data are available on the structure of human light chain variable region genes, but the variable regions of over 150 human κ light chain proteins have been sequenced and they comprise four distinct subgroups<sup>3–5</sup>. Here we report the complete DNA sequences of three human κ variable region (V<sub>κ</sub>) genes isolated from fetal liver DNA. The sequences demonstrate that two non-allelic genes encoding subgroup I proteins have more than 90% nucleotide homology in both coding and non-coding regions. Comparison of these human genes with two complete DNA sequences of mouse V<sub>κ</sub> genes<sup>6,7</sup> shows that V<sub>κ</sub> gene structure is highly conserved between the two species, which suggests that V<sub>κ</sub> genes rearrange during the differentiation of human lymphocytes by a very similar mechanism to that in the mouse<sup>8,9</sup>. The sequence of a defective

$V_{\kappa}$  gene is also described—this gene is unable to code for a functional immunoglobulin due to substitutions, deletions and insertions in its sequence. It is analogous to the pseudogenes<sup>10</sup> of globin<sup>11-13</sup> and *Xenopus* 5S RNA<sup>14</sup>.

To isolate human  $V_{\kappa}$  genes, we used the ability of mouse and human  $V$  gene sequences to cross-hybridize<sup>15</sup>. A mouse  $V_{\kappa}$  plus constant region cDNA clone derived from MPC11 plasmacytoma cells<sup>16</sup> was used as a probe to screen a library of fragments of human fetal liver DNA<sup>17</sup> cloned in the  $\lambda$  phage vector, Charon 4A (ref. 18). About 150,000 clones were screened and one hybridizing clone, HK101, was isolated. Restriction fragments containing the  $V_{\kappa}$  coding region were subcloned in an M13 phage vector<sup>19</sup> and sequenced by the chain-terminator method<sup>20,21</sup>.

The DNA sequence of the HK101  $V_{\kappa}$  gene is shown in Fig. 1. The predicted amino acid sequence was compared with the protein sequences of human  $\kappa$  light chains<sup>3</sup> which allowed this gene to be assigned to the  $V_{\kappa}I$  subgroup. Comparison with two mouse  $V_{\kappa}$  genes that have been completely sequenced<sup>6,7</sup> showed that the gene apparently codes for a hydrophobic signal peptide 22 amino acids long and the first 95 V-region residues of the secreted protein. This analysis also allowed us to identify a 125-base intervening sequence within the region coding for the signal peptide. The absence of a J region sequence shows that this V gene is in the germ-line configuration, that is, it has not undergone V-J joining.

Figure 1 compares the sequences of the human  $V_{\kappa}$  gene HK101 and the mouse  $V_{\kappa}$  gene K2 (ref. 7) and demonstrates

that  $V_{\kappa}$  gene structure is conserved between man and mouse. One conserved feature of the structural gene is the position of the intervening sequence between amino acids -4 and -5 of the signal peptide. The intervening sequence of human<sup>22</sup> and mouse<sup>23</sup> heavy chain V genes is also located at this position. Both human and mouse  $V_{\kappa}$  genes only encode amino acids up to position 95 of the complete light chain. Thus  $\kappa$  light chain genes of both species are interrupted within the third antigen-binding or complementarity-determining region at position 95. This implies that in man, as in the mouse, the carboxy-terminal portion of a  $V_{\kappa}$  region is encoded by a separate  $J_{\kappa}$  gene.

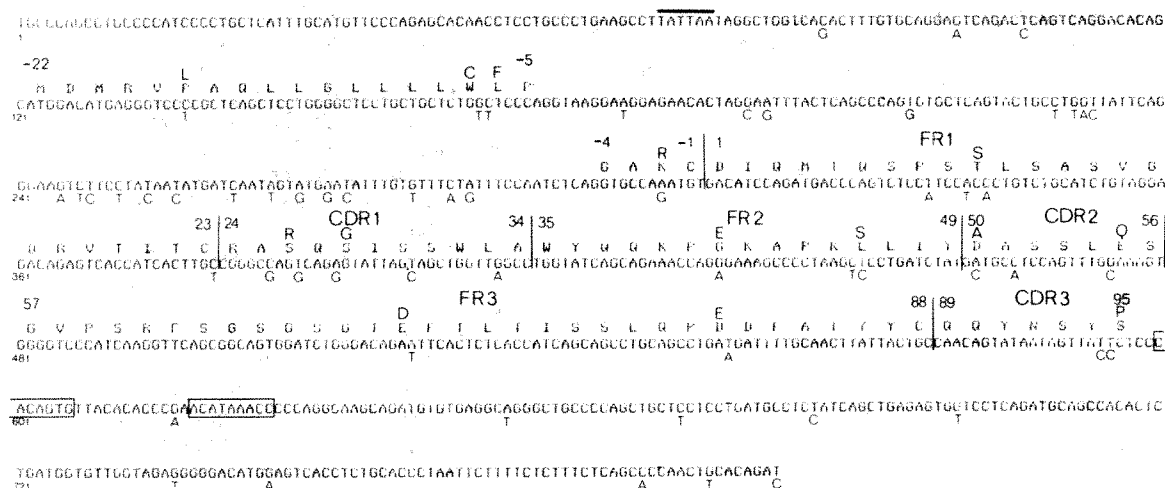

Also conserved between man and mouse are two short lengths of sequence adjacent to the 3' side (downstream) of the  $V_{\kappa}$  genes (see Fig. 1) that are thought to be recognized by the mechanism which joins V and J segments to create a complete immunoglobulin gene<sup>8,9</sup>. These 'V-J joining sequences', 7 and 9 bases long, are identical in the human HK101 gene and the mouse K2 and MOPC 41 genes<sup>6,7</sup>. Closely related sequences have been found adjacent to variable region genes of mouse  $\lambda$  light chains<sup>24</sup> as well as human<sup>22</sup> and mouse heavy chains<sup>23</sup>. These observations imply that very similar gene-rearrangement mechanisms operate on mouse and human light and heavy chain V genes.

The two coding segments of the human HK101 gene are 75% and 76% homologous to the mouse sequences MOPC 41 and K2 whereas the intervening sequences have only 50% and 60% homology. More rapid evolutionary divergence of intervening sequences relative to coding sequences has also been observed for globin<sup>25</sup>, vitellogenin<sup>26</sup> and insulin genes<sup>27</sup>. However, the 5'

**Fig. 1** Sequence comparison of human (HK101) and mouse (K2)<sup>7</sup>  $V_{\kappa}$  genes. The HK101 gene was isolated from a library of human fetal liver DNA fragments cloned in Charon 4A (ref. 17) by plaque-hybridization screening<sup>36</sup> using the nick-translated<sup>37</sup> mouse  $V_{\kappa} + C_{\kappa}$  cDNA clone  $\mu\kappa(11)24$  (ref. 16) as a probe. The HK101 V gene was identified within a 4.8-kilobase fragment of the recombinant  $\lambda$  phage by Southern blot hybridization<sup>29</sup> using  $\mu\kappa(11)24$  as the probe. This fragment was subcloned in the plasmid pBR322 and the *Pst*I sites within the insert were mapped by the method of Smith and Birnstiel<sup>38</sup>. Two *Pst*I fragments (with junctions at codons 79/80) containing the coding region were cloned in the phage vector M13mp2/*Pst*, which was constructed by blunt-end ligation of a *Pst*I linker octanucleotide to the *Eco*RI site of M13mp2 (ref. 19) which had been filled with the Klenow fragment of *Pol*I (ref. 39). The single-stranded DNA of recombinant M13 phage was used as a template for sequencing by the chain-terminator method<sup>20,21</sup> with a 26-base pair primer<sup>40</sup>. Although we have not sequenced over the junction of these two *Pst*I fragments, their alignment was derived from restriction mapping data and from sequencing of a closely related gene, HK102, where we sequenced through the *Pst*I site at this position. In the two sequences shown, broken lines have been inserted to maximize homology between the human and mouse genes using the computer program XMATCH<sup>41</sup>. The derived protein sequence is given in the one letter code. The framework (FR) and complementarity-determining (CDR) regions of the protein are indicated. The two 'V-J joining sequences' are boxed.

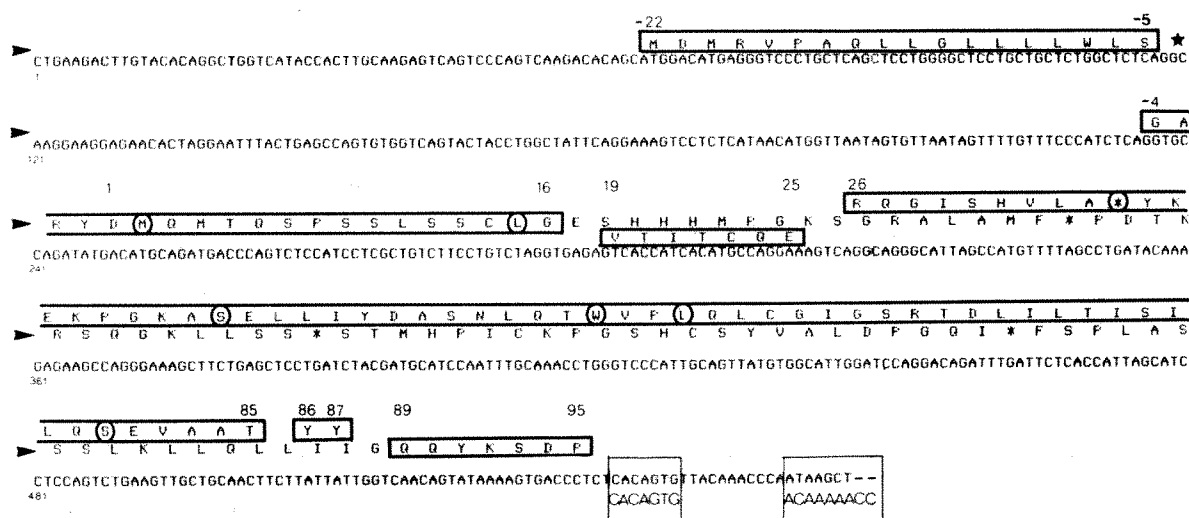

**Fig. 2** Sequence of a second human V $\kappa$  gene, HK102. The HK102 gene was selected from the library of cloned human DNA fragments using as probe the HK101 *Pst*I fragment coding up to amino acid 79 subcloned in the plasmid pBR322. The HK102 V gene was sequenced by a rapid procedure in which recombinant  $\lambda$  phage DNA was digested with a restriction enzyme to yield a mixture of small (<500 base pairs) fragments which was then 'shotgun' cloned into an M13 vector treated with phosphatase to prevent self-ligation<sup>42</sup>. The resulting recombinants containing fragments of the variable region coding sequence were selected by plaque hybridization screening<sup>36</sup> using the HK101 V segment probe. *Sau*3A fragments were cloned in M13mp2/Bam<sup>43</sup> and *Alu*I fragments in M13mp73 (J. Messing, unpublished results). Use of two restriction enzymes made it possible to overlap all junctions between fragments except for the junction between *Alu*I fragments at position -15/-14 of the protein. These two fragments were aligned by analogy with the HK101 sequence. 58% of the sequence was obtained on both strands derived from independent M13 clones. The HK101 V $\kappa$  nucleotide and amino acid sequences are marked at points where they differ from HK102. A sequence related to the TATAAA box important for the initiation of transcription by RNA polymerase II in other genes<sup>44</sup> is overlined. The 'V-J joining sequences' are boxed.

and 3' sequences closely flanking mouse and human V $\kappa$  genes are as homologous as the coding regions. In the 130 bases 5' (upstream) of the first codon, HK101 and K2 are 72% homologous (excluding an insertion of 10 bases in the human sequence) and in the 90 bases 3' of the last codon they are 74% homologous. Further downstream no significant homology could be detected. The conservation of non-coding flanking sequences may suggest that they have functional significance for transcription or gene rearrangement but these predictions require experimental verification. It is apparent from the comparison of mouse and human V $\kappa$  genes that during evolution non-coding sequences diverge from one another in different ways from coding sequences. Divergent coding regions are related primarily by base substitutions, whereas non-coding regions also

contain insertions, deletions and duplications as observed for the mouse  $\beta$ -globin genes<sup>28</sup> and *Xenopus* vitellogenin genes<sup>26</sup>.

As a first step towards a full description of diversity among germ-line V $\kappa$  genes we have isolated and sequenced two other human V $\kappa$  genes. The sequence of one of these, HK102, is shown in Fig. 2. HK101 and HK102 are probably non-allelic V $\kappa$  genes because we have identified restriction fragments corresponding to both of these in the DNA from each of 7 unrelated individuals using the Southern hybridization technique<sup>29</sup> (D.L.B. and T.H.R., in preparation). The HK101 and HK102 V $\kappa$  genes are more than 94% homologous throughout the coding region and the 5' and 3' flanking sequences (Fig. 2), and, as in the mouse-human comparison (Fig. 1), the intervening sequences are considerably less homologous (82%) than the

**Fig. 3** The DNA sequence of a human V $\kappa$  pseudogene. Isolation of the gene, HK100, and the DNA sequencing strategy was as for HK102 (Fig. 2 legend). All junctions between *Alu*I and *Sau*3A fragments were sequenced. 92% of the sequence was obtained in both strands and the region where only one strand was sequenced was confirmed on two independent clones. The in-phase reading frame is indicated with arrows. The reading frames which correspond to normal immunoglobulin protein are in heavy boxes and amino acid positions are marked according to the standard numbering of normal  $\kappa$  light chains<sup>3</sup>. Asterisks mark termination codons and circles mark positions where highly conserved amino acids have been replaced due to apparent base-pair substitutions. The unconventional sequence at the 5' end of the intervening sequence is indicated by a star. Putative 'V-J joining sequences' are in light boxes. The final two blank positions refer to unidentified nucleotides beyond the *Alu*I fragment sequenced.

coding and flanking sequences. Both the HK101 and HK102 genes encode proteins that can be assigned to the  $V_{\alpha}Ib^{30}$  subgroup but neither is identical to any known complete protein sequence. However, the HK102 sequence is closely related to the EU light chain protein<sup>31</sup> from which it differs by 6 amino acids in the first 95. HK101 and HK102 differ at 14 amino acid residues in the signal peptide and in each of the framework and complementarity-determining regions of the protein. It seems likely that the extensive homology between these two human sequences is due to their recent common ancestry or to some gene correction mechanism<sup>32</sup>.

The sequence of a third human  $V_{\alpha}$  gene, HK100 (Fig. 3), is remarkable because it apparently cannot encode a functional immunoglobulin. The reading frame of this gene contains three in-phase termination codons which are a result of four small insertions and deletions in the DNA sequence relative to normal  $V_{\alpha}$  genes such as HK101 or HK102. These apparent mutations are a 2-base deletion at amino acid position 17/18, a 4-base insertion at 25/26, a 3-base insertion at 85/86 and a 1-base insertion in the invariant Cys codon at position 88. In addition, a number of apparent nucleotide substitutions in the coding region of HK100 change highly conserved amino acid residues at positions 2, 15, 44, 57, 60 and 80. A substitution at amino acid 35 replaces an invariant Trp codon, TGG, with a TGA nonsense codon (which is not in phase, however). Overall, the sequence of this abnormal gene and its flanking regions is 78% homologous to the HK101 sequence after maximizing homology<sup>41</sup>. The sequence of the HK100  $V_{\alpha}$  gene suggests that it evolved by a mechanism typical of non-coding sequences, involving insertions and deletions as well as substitutions.

We do not know whether the HK100 V gene is capable of being transcribed but it is unlikely that a transcript could be correctly processed. The 5' end of the intervening sequence begins with a GC dinucleotide, not the highly conserved GT normally found at this position<sup>33</sup>. This GC sequence has never been observed in 36 known functional RNA splicing sites<sup>34</sup>.

Furthermore the HK100  $V_{\alpha}$  gene may not be able to undergo V-J joining. Examination of the two sequence blocks downstream of the gene, thought to be important for V gene rearrangement, shows that the HK100 sequence possesses the first CACAGTG block but lacks a good match with the ACAAAAACC consensus sequence for the second block. In fact it differs from the consensus at four of the first seven positions (see Fig. 1) whereas no other known  $V_{\alpha}$  gene differs from the consensus at more than one position<sup>35</sup>.

Other genes apparently unable to encode functional products have been discovered for 5S rRNA and  $\alpha$  and  $\beta$  globin (see ref. 10 for a review) and these have been termed pseudogenes. The HK100  $V_{\alpha}$  gene is the first example of an immunoglobulin variable region pseudogene.

We thank Dr T. Maniatis for providing the library of cloned human DNA and Drs Perry, Marcu and Schibler for the plasmid p $\alpha$ (11)24 (ref. 16), J. Karn for Sau3A, and B. J. Meyer, J. Sims and S. Fields for critical reading of the manuscript.

## Dimethyl sulphoxide reduces anti-receptor antibody titres in experimental myasthenia gravis

Alan Pestronk & Daniel B. Drachman

Johns Hopkins University, School of Medicine, Department of Neurology, 1721 E. Madison Street, Baltimore, Maryland 21205

The basic abnormality in myasthenia gravis (MG) is a reduction of acetylcholine receptors (AChRs) at neuromuscular junctions, due to an autoimmune attack directed against the receptors<sup>1</sup>. Several lines of evidence support the idea that humoral immune mechanisms play an important part in this process: anti-AChR antibodies are present in the sera of more than 80% of myasthenic patients<sup>2-4</sup>; the pathogenicity of the antibodies has been demonstrated by passive transfer of IgG from myasthenic patients to mice which reproduces the typical features of MG in the recipient animals<sup>5,6</sup>; finally, procedures that reduce levels of anti-AChR antibody, such as plasmapheresis, produce improvement in the clinical symptoms of MG<sup>7</sup>. Present treatments of MG depend largely on the prolonged use of immunosuppressive drugs, which have significant drawbacks<sup>1,8-10</sup>, for they usually produce only a slow fall in antibody titres, and have toxic side effects. An agent that could produce a rapid and sustained fall of autoantibody titre might have wide application in the treatment of MG and other autoimmune diseases. In the course of testing immunosuppressive drugs for their effect in treating experimental autoimmune MG (EAMG), we discovered that the vehicle used to dissolve some of these agents, dimethyl sulphoxide (DMSO), itself produced a rapid and sustained fall of anti-AChR antibody titre. We now report similar results for a controlled trial of DMSO treatment in rats with EAMG.

EAMG was produced in female Lewis rats (200-225 g) by immunizing them with 50  $\mu$ g of AChR, emulsified in an equal volume of Freund's complete adjuvant, injected intradermally. AChR was extracted from the electric organs of *Torpedo californicus* with Triton X-100 and purified by affinity chromatography, using  $\alpha$ -toxin from the venom of the cobra *Naja naja siamensis* covalently linked to Sepharose 4B beads as the binding ligand<sup>11</sup>.

Measurement of anti-AChR antibodies was carried out by a double precipitation radioimmunoassay like those previously described<sup>2,4</sup>. Antibodies directed against *Torpedo* AChR were measured using as the antigen  $0.5 \times 10^{-12}$  moles of purified *Torpedo* AChR coupled to <sup>125</sup>I- $\alpha$ -bungarotoxin (<sup>125</sup>I- $\alpha$ -BTX). Serial dilutions of sera from the experimental rats were used, and precipitation was produced by the addition of goat anti-rat IgG. The antibody titre, determined from the linear portion of the dilution curve, is expressed as moles  $\times 10^{-9}$  of  $\alpha$ -BTX precipitated per litre. For determinations of antibody against rat AChR, an aliquot of Triton-extracted denervated rat muscle containing  $0.5 \times 10^{-12}$  moles of AChR was used as the antigen,

coupled to  $^{125}\text{I}$ - $\alpha$ -BTX as above. These assays were sensitive to antibody concentrations of  $0.5 \times 10^{-9}$  moles per l of serum. Determinations of antibodies against both *Torpedo* AChR (the immunizing antigen) and rat AChR (the 'self' antigen) were made repeatedly up to 2 months after the start of the experiment. Levels of rat IgG were measured in sera from treated and control EAMG animals by a commercial radial immunodiffusion assay (Hyland).

The original purpose of our investigations was to examine whether frentizole, a drug thought to be particularly effective in suppressing humoral immune responses, would reduce the levels of anti-AChR antibody in rats with EAMG. Because frentizole is poorly soluble in water it was administered in DMSO solution; control EAMG animals received DMSO alone. Our results showed that anti-AChR titres fell by 50% within 1 week in both experimental and control animals.

A therapeutic trial of DMSO alone was therefore undertaken to determine whether DMSO was responsible for the fall in the antibody titre. Experimental rats with EAMG were treated with a 2-week course of daily intraperitoneal injections of DMSO (1.0 ml) starting 1 month after immunization with AChR. Control EAMG animals immunized at the same time were given injections of physiological saline.

After 1 week of treatment with DMSO the titre of anti-*Torpedo* AChR antibody decreased to a mean of 46% of pretreatment levels. The titres remained markedly reduced, reaching 32% of pretreatment levels 6 weeks after discontinuation (Fig. 1a). In contrast, antibody titres in control animals remained elevated, eventually rising to a level 30% higher than that at the start of the study (Fig. 1a). There was also a rapid reduction in levels of the autoantibody, against rat AChR. One week after the start of DMSO treatment anti-rat AChR antibody titres had fallen to 48% of pretreatment levels (Fig. 1b). By the end of the study, the mean anti-rat AChR antibody titre was 14% of the pretreatment level, and 12% of the level in untreated controls. In control animals autoantibody titres remained relatively constant, averaging 5% higher at the end of the study. Serum concentrations of IgG were initially reduced by DMSO treatment, being 42% of pretreatment levels after 1 week. However, in contrast to the anti-AChR antibody, IgG rapidly returned to pretreatment levels (Fig. 2). By 2 weeks after the end of the treatment course, the mean IgG level was not significantly different from the levels in pretreatment or control animals.

We carried out additional control experiments which showed that DMSO did not interfere with the assay for anti-AChR antibody. Antibody titres were not significantly affected by levels of DMSO of up to 0.5% in serum. Further, antibody titres

**Fig. 1** a, Antibody titres against *Torpedo* AChR; b, antibody titres against rat AChR. Dashed line indicates titres in untreated EAMG rats, solid line those in DMSO-treated EAMG rats. Treatment was given at time 0 (4 weeks after induction of EAMG). Antibody titres at time 0 were normalized to 100%. The absolute values of antibody at this time were  $640\text{--}2,300 \text{ mol} \times 10^{-9} \text{ l}^{-1}$  against *Torpedo* AChR and  $5\text{--}60 \text{ mol} \times 10^{-9} \text{ l}^{-1}$  against rat AChR. Subsequent values represent the mean of percentages of the initial titre (from eight treated and seven untreated rats)  $\pm$  s.e.

**Fig. 2** Levels of total IgG. Dashed line indicates levels in untreated EAMG rats, solid line those in DMSO-treated EAMG rats. Treatment was given at time 0 (4 weeks after induction of EAMG).

in EAMG animals treated 8 h previously with a single dose of DMSO did not differ from titres in untreated animals.

Our results show that treatment with DMSO reduced antibody titres against both foreign (*Torpedo*) and self (rat) AChR. The fall in titres was rapid and sustained, and titres did not rise even after DMSO was discontinued. The mechanism by which DMSO reduces antibody titres is unknown. The fall in anti-AChR antibody titres is not attributable to a direct effect of DMSO on the antibody, as there was no change in the titre after acute treatment with DMSO. The effect is not due to interference with the antibody assay, because relatively high serum concentrations of DMSO had no effect on antibody measurement. In addition, the half life of DMSO is less than 1 day<sup>12</sup> and anti-AChR antibody titres remained low for at least 6 weeks after the cessation of treatment. A more likely explanation for the fall in titres is that DMSO reduced the production of antibody by lymphoid cells. It remains to be determined whether this effect is due to a direct action of DMSO on antibody-producing cells or to an indirect effect on immune regulatory mechanisms such as suppressor cells. In any case, active immune responses may be especially susceptible to DMSO, for anti-AChR antibody titres remained low, whereas the total IgG concentration returned to normal.

It is encouraging that the fall of anti-AChR antibody titres after DMSO treatment is comparable to that which results from plasmapheresis. This suggests that DMSO might be effective in the treatment of diseases such as MG where antibodies have an important pathogenic role<sup>1</sup> and plasmapheresis provides only temporary improvement<sup>7</sup>. The finding that at the longer times after treatment, autoantibodies against AChR remained depressed whereas the total levels of IgG returned to normal may be relevant to the potential usefulness of DMSO in human disease states.

Thus, we have found that DMSO treatment produces a rapid and sustained fall in anti-AChR antibody in EAMG. It seems likely that DMSO might also be effective in ameliorating other active humoral immune responses. If so, DMSO may provide an effective new treatment for immune diseases mediated by autoantibodies.

# Anomalous region on Mars: implications for near-surface liquid water\*

S. H. Zisk

NEROC Haystack Observatory, Westford, Massachusetts 01886

P. J. Mouginis-Mark

Department of Geological Sciences, Brown University, Providence, Rhode Island 02912

*An anomalous region has been identified on Mars from the 1971 and 1973 Earth-based Goldstone radar data. This region is characterized by coincident very high radar reflectivities, and unusual smoothness. Very few realistic surface morphologies can generate such return-signals. Liquid water within ~50–100 cm of the surface is one possibility, an interpretation strengthened by an apparent seasonal variation in surface reflectivity for the same locality.*

ANALYSIS of radar measurements of the martian surface enables textural-compositional differences of materials to be interpreted on a scale unobtainable from orbital images<sup>1–3</sup>. Estimates of the dielectric constant (from inherent reflectivity) and small-scale slope statistics (see, for example, the C-factor analysis developed by Hagfors<sup>4</sup>) can be used to characterize surface units<sup>5</sup> or to delineate areas with unusual material properties.

An extensive data base was compiled from Earth-based radar measurements of the martian surface by Downs *et al.*<sup>2</sup> in 1971 and 1973 at the Jet Propulsion Laboratory's Goldstone Facility. This combined set of observations gave almost complete coverage between 14 and 22° S. The high dielectric constant of liquid water compared with both ice and dry geological materials<sup>6</sup> means that radar observations should provide excellent evidence for or against the existence of water on Mars. In particular, this radar data set can provide additional evidence regarding the existence of near-equatorial regions of H<sub>2</sub>O outgassing ('oases') proposed by Huguenin *et al.*<sup>7,8</sup>. Liquid water should affect the radar characteristics of the surface, if any overburden is relatively transparent to the radar energy. If the water were allowed to form a free surface, as opposed to an adsorbed layer on a mineral substrate, then the radar-reflecting facets would be expected to be nearly horizontal due to gravitational forces. Hence this type of surface would give a radar return with a very high smoothness as well as high reflectivity. We report here our attempts to search for anomalous areas within the radar data set, where both high reflectivity and C-factor values could be attributed to a layer of liquid water or damp soil.

## Experimental method

The radar determination of surface smoothness and reflectivity is derived from the observed variation of echo strength as a function of local incidence angle<sup>4,6</sup>. The radar echo at any incidence angle is the incoherent sum of reflections from surface facets within the resolution cell which are oriented perpendicular to the radar beam. Strictly speaking, the reflecting surfaces are the Fresnel zones of these elements, so that the cross-section of each surface element depends on its radius of curvature or, where the radius is large, on its area<sup>6</sup>. The size of the radar

resolution cell is much larger than even the planetary-radius Fresnel zone. It is fixed by the resolution of the radar signal in time-delay and Doppler frequency, which respectively determine the resolution along the projected axis of rotation and at right angles to it. For the radar data considered here, the resolution cell measures ~80 km by 10 km, compared with the 0.9-km size of the Fresnel zone for the planet's radius of curvature<sup>2</sup>.

The C-factor parameter used to describe the surface smoothness quantitatively was derived by Hagfors<sup>4</sup>. He postulated a set of models for surface topography (based on observations of the Moon), for each of which he calculated the number distribution of surface-facet slopes, and thence the expected curve of radar strength compared with incidence angle (C-factor template). The radar-observed curve was computer-fitted to these hypothetical curves to determine the best-fit value for the C-factor. For areas with moderate to high smoothness (C-factor > 100), the expression for the r.m.s. surface slope  $a_{rms}$  is

$$a_{rms} = C^{-1/2} \text{ rad}$$

For real surfaces which do not match these models, the measured curve of echo strength compared with the incidence angle will not agree well with any of the templates, and a large standard error will result from the fitting process. Smooth, random surfaces will generally show a good fit to the templates, because there is little dependence on the details of the model. Surfaces with high relief, on the other hand, cannot usually be described well by only one parameter. Also, a non-random surface such as an area of sand-dunes or a cluster of comparable-size craters, cannot be described well by the standard C-factor parameter at any observable amplitude of relief.

The morphology of the surface determines the shape of the curve and hence the value of C-factor. The amplitude of the curve is a function only of the reflectivity of the material of which the surface is composed, and is another independent output from the template-fitting process.

In the present radar measurements, the same surface-resolution element was observed at various incidence angles (by using the Doppler resolution in longitude) to form the curve of echo strength versus incidence angle. There is therefore no implicit

\* **Erratum:** Due to an error in the *Nature* office, the original rather than the subsequently revised version of this article appeared in the issue of 13 November (288, 126–129, 1980). We here reprint the article in its correct form.

**Fig. 1** Number density of radar sample points with given characteristics per  $1^\circ$  latitude,  $5^\circ$  longitude sample bins. *a*, Reflectivity  $>9\%$  and *C*-factor  $>3,200$  coincidentally; *b*, *C*-factor  $>3,200$ ; *c*, reflectivity  $>9\%$ . Note that although data points with high reflectivity or *C*-factor occur over a wide area of Mars, coincident high values in both parameters are found exclusively at the 'oasis' areas proposed by Huguenin *et al.*<sup>7,8</sup> (Solis Lacus, at  $15\text{--}30^\circ$  S,  $80\text{--}90^\circ$  W; and Noachis-Hellespontus, at  $15\text{--}25^\circ$  S,  $305\text{--}315^\circ$  W).

assumption of large-area uniformity of the surface, as was the case for some earlier measurements. Any systematic variation in surface composition as, for example, a low-reflectivity mantled surface interspersed with high-relief, high-reflectivity rock formations, will show up as a poor fit (high standard error) to the *C*-factor templates<sup>5</sup>. A mixture of high- and low-reflectivity materials exhibiting the same morphology will yield a low-error *C*-factor value, with an intermediate reflectivity. Other surface configurations can be hypothesized and their radar-measured parameters calculated. The reverse calculation, however, from the radar data to the surface configuration, cannot be carried out unambiguously for all combinations of reflectivity and *C*-factor. As the surface becomes less smooth, the variety of possible configurations increases and the reliability of the template-fitting becomes much worse, partly because of the reduced strength of the widely-scattered signal and partly because of the above-mentioned variety of possible surface topographies.

## Analysis

The data were scanned for regions with a coincident high reflectivity and smoothness. Limits of  $9\%$  reflectivity and  $3,200$  *C*-factor (r.m.s. slopes  $<1^\circ$ ) were chosen arbitrarily. Variations from  $9$  to  $11\%$  and from  $2,400$  to  $3,200$  respectively had only a slight effect on the shape of the anomalous area and on the number of observation points. For these measurement values, the formal errors (standard deviations) were  $\sim 10\%$  of the data value.

Figure 1*a* illustrates the areocentric position and number densities of these high-reflectivity, high-smoothness measurements. Only two regions on the planet share this combined radar characteristic. The most prominent is a region centred at  $16^\circ$  S  $90^\circ$  W. There is also a pair of smaller areas to the north-west of Hellas. These two regions are remarkably close to the Solis Lacus ( $25^\circ$  S,  $85^\circ$  W) and Noachis-Hellespontus ( $20^\circ$  S,  $310^\circ$  W) proposed by Huguenin *et al.*<sup>7,8</sup>.

For comparison, Fig. 1*b,c* indicates the areas having only their reflectivity or *C*-factor above the defined limits. Note that there are many areas of high reflectivity, indicating a profusion of well-compacted or rocky soils on the martian surface. Areas of high smoothness are less common, although they are not restricted to the anomalies described here.

As an argument for the reality of the anomalous areas, note that the map of Fig. 1*a* includes radar measurements from both the 1971 and 1973 conjunctions. Almost no anomalous data points occur elsewhere on the planet, despite the near-global coverage of the data set between  $14$  and  $22^\circ$  S. In the  $300 \times 300$  km anomaly itself, on the other hand, there are several hundred points.

## Seasonal variability

Additional characteristics of Solis Lacus can be determined by comparing radar data derived for nearly coincident ground tracks at different times of the martian year. Note that practical limitations of Earth-based radar systems dictate that radar observations of the sub-Earth region must be made near opposition, and hence near local martian summer. Winter measurements would at best be extremely difficult to make using Earth-based radar.

A combination of data from the 1971 and 1973 oppositions provides an example of overlapping radar swaths: latitudes  $15.45^\circ$  S,  $15.43^\circ$  S, and  $15.81^\circ$  S were sampled between  $80$  and  $100^\circ$  W during the seasonal range from early to middle local martian summer ( $L_s = 258^\circ$ ,  $273^\circ$  and  $294^\circ$  respectively). Note that, as  $L_s$  represents the longitude of the Sun as seen from Mars, the difference between  $L_s = 258^\circ$  and  $294^\circ$  is roughly equivalent to the shift from early June to mid-July on Earth (Northern Hemisphere). Because of the nearly identical locations of these radar profiles (the north-south extent of the radar resolution cell is  $1.3^\circ$ , giving an overlap of at least  $70\%$  between swaths), the reflectivity curves for identical surfaces should be very similar. However, Fig. 2 indicates that there is a discrepancy in the reflectivity between  $L_s = 258^\circ$  and  $273^\circ$ . The  $273^\circ$  profile indicates an increase of  $1.0\text{--}1.5\%$  in the reflectivity compared to the same longitude at  $L_s = 258^\circ$ , while the  $294^\circ$  profile shows a further enhancement of  $2.5\text{--}3.5\%$ . For large parts of the region between  $82$  and  $100^\circ$  W, there is a systematically higher reflectivity with advancing  $L_s$ , that is season. Such a

**Fig. 2** Temporal variations in radar reflectivity for an area of Solis Lacus at  $15.43\text{--}15.81^\circ$  S. Curves represent a running 5-point average at  $0.16^\circ$  longitude intervals. Radar data was taken during 1971 ( $L_s = 258^\circ$ ) and 1973 ( $L_s = 273^\circ$  and  $294^\circ$ ) Mars oppositions at latitudes  $15.44$ ,  $15.43$  and  $15.81^\circ$  S respectively. The 'anomalous areas' refer to parts of the ground track at  $L_s = 294^\circ$  where reflectivity is  $>9\%$  and *C*-factor  $>3,200$  (see also Fig. 4*a*).

**Fig. 3** The seasonal variations in radar reflectivity compared here for three regions of Mars. The horizontal axis is reflectivity and the vertical axis is the percentage of data points having less than the indicated reflectivity. *a*, Compares the strongly anomalous Solis Lacus area with the weakly anomalous Noachis-Hellespontus region. *b*, Compares Solis Lacus with an area in Aeolis, which is taken to be representative of Mars as a whole and shows no anomaly. Note that all three areas display an increase in percentage reflectivity with increasing martian season, but that Solis Lacus has a much more pronounced seasonal change, in addition to its higher absolute radar reflectivity.

**Fig. 4** Viking Orbiter Images of the anomalous radar areas. *a*, Ground track shown in Fig. 2; *b*, high resolution for an area in Solis Lacus at 18.7°S. Note that the images do not support a hypothetical smooth, mantle-free surface as an explanation of the radar anomaly. Numerous 10-km craters and lava flow fronts are in evidence (USGS photomosaics I-1183 and I-1190; and Viking frame 773A10). Scale bar, 3 km.

phenomenon seems to be real, since some parts of the data (for example, between 83–84° W and 88–92° W for  $L_s = 258^\circ$  and  $273^\circ$ ) show no difference in reflectivity despite their respective acquisition dates in 1971 and 1973. This is strong evidence for the adequacy of the calibration of the original radar data, and also for the lack of any temporal variation in the data from instrumental causes.

In another test for possible systematic effects, we are searching the radar data at areas other than the observed anomaly for quasi-seasonal variability. Some of the results are depicted in Fig. 3. Figure 3a presents a plot of the range of variability of the reflectivity with  $L_s$  for Noachis-Hellespontus, which contains the only cluster of anomalous points outside the Solis Lacus region. Figure 3b presents Aeolis as an example of a non-anomalous region. Figure 3 shows that there is a 'seasonal' variability in much of the observed area, in the same sense (increased reflectivity with advancing summer); but that Solis Lacus exhibits the greatest range by more than a factor of 2 of those areas so far examined. The general variability may indicate scattered expressions of near-surface water and/or permafrost; or possibly a low-level, systematic and time-dependent flaw in the calibration.

## Discussion

Measurements showing a high radar reflectivity (high dielectric constant) would be expected not only for water surfaces, but also for large areas of smooth rock within 1 m of the surface. In these conditions, anorthositic rock, with a dielectric constant  $K$  of about 5, would have a reflectivity of about 15% (basalt, with  $K = 9$ , is >25%; water, with  $K = 81$ , is >65%) if it covered the entire surface area of the radar cell (~750 km<sup>2</sup>). Figure 4 presents Viking Orbiter images of the same area as Fig. 2. Although few craters larger than ~10 km diameter are within the radar ground track, many moderately well preserved lava flow fronts can be easily identified. Morphologically comparable lava flows elsewhere on Mars either have radar reflectivities of 2–6% or  $C$ -factors <2,000 (refs 5, 9, 10). Unless the small-scale surface texture of the Solis Lacus region is unrelated to its large-scale appearance in Fig. 3, the hypothesis of an extensive rock pediment is untenable as an explanation for the high values of radar reflectivity and  $C$ -factor.

Moreover, to explain a seasonal variability in the reflectivity of a solid rock surface, one must hypothesize, for example, an absorptive overburden which is regularly scoured away as the summer progresses. The thickness of overburden required for the observed changes in dielectric constant have been calculated on the basis of published dielectric constants and absorption lengths for basaltic rock and loosely-compacted rock powder<sup>11</sup>. Although resonant effects of thin highly-planar soil and rock layers might be observed in laboratory conditions, such conditions do not exist on a planetary surface. Consequently, the reflectivity was calculated for a random-thickness soil layer masking a solid rock surface. Assuming dielectric constants of 2.0 for soil and 8.0 for rock, the net reflection coefficient for bare rock is 23%; for a soil layer at least 14 cm (one wavelength) thick, is 11%; and drops to 6% for a soil depth of 1.4 m. For lunar rock chemistry rather than terrestrial rock chemistry, the 6% reflectivity would require more than 10 m of rock-free soil. The problem is complicated by other factors such as variation in

soil porosity with depth, but the conclusion, nevertheless, is that for rock and soil surface to exhibit a measured reflectivity of more than 11%, the soil thickness must be in the range from 10 to 20 cm over the entire area; and that an additional deposit of the order of 1 m of soil would be required to reduce further the dielectric constant to 8%. Although there is undoubtedly a seasonal redistribution of martian dust, photographs at the Viking Lander sites<sup>12</sup> do not show the buildup of the tens of centimetres of dust that would be needed to effect a change from 11 to 8% in the average radar reflectivity. Alternative explanations, such as seasonal changes in the bulk chemistry of the near-surface rocks, seem also to be unlikely.

Conversely, a transition from frozen water (reflectivity >7%) to liquid water (reflectivity >64%) would produce just such a striking difference in the observed radar reflectivity. Considerable supporting evidence exists that permits the presence of liquid water on Mars to be hypothesized. The large martian channel systems are believed to be the products of large-scale release and surface flow of water from confined aquifers<sup>13,14</sup>. Thermal and IR-spectral measurements of the North Polar cap<sup>15</sup> indicate abundant water ice, while 1–3 wt% of adsorbed water was detected in samples taken by the Viking Landers<sup>16</sup>. In addition, on a smaller scale, both spectrophotometer measurements made during the 1973 dust storm<sup>17</sup> and measurements from the Viking water-vapour mapping experiment<sup>18</sup> indicate that a considerable amount of H<sub>2</sub>O outgassing occurs at present within Solis Lacus. Although the surface temperatures at the Viking Lander sites are only in the range 230–250 K (ref. 19), for an assumed analogy with terrestrial geology the water reservoir could be highly saline due to the salts leached from the surrounding rocks<sup>20</sup>. For Mars, saline solutions have been shown to be stable in their liquid phase in current surface conditions at temperatures as low as 210 K (ref. 21).

We conclude, therefore, that only surface materials containing liquid water are consistent with: (1) the coincident very high radar reflectivities and  $C$ -factor values; (2) the photographically observed surface morphology; and (3) the increase in reflectivity values from spring to summer. Some inferences can also be made about the regional extent of the near-surface expression of the liquid water at Solis Lacus. An extensive liquid water surface (such as a lake) would have a much higher reflectivity than the observed maximum value of about 16%. More likely is a reduction in the reflectivity by an overlying layer of soil, as outlined above for the rock-soil combination, or, alternatively (or additionally), the liquid water might be observable only through random patches of the surface because of variations in the thickness or density of the overburden. In the latter case, the observed reflection values would be from a mixture of high and low reflectivity surface elements. In this case, the  $C$ -factor measurements would depend mainly on the highly reflecting regions (the oases) rather than the dry intervening areas. In either case, we are convinced by the radar data that liquid water does indeed exist near the surface of Solis Lacus during Southern Hemisphere summer.

We thank George Downs for radar data, and Richard Simpson and Gordon Pettengill for helpful comments. This research was partly supported by NASA under grants NSG-7179, NSG-7569, and NSG-7570. Haystack Observatory is operated by MIT under NSF grant AST-7920168.

## MATTERS ARISING

## Superoxide involvement in negative air ion effects

INTEREST in research on the biological effects of small negative air ions has been due to the variety of claims made for them, ranging from lethal effects on micro-organisms to therapeutic effects on humans<sup>1-3</sup>. In spite of the promising results reported, there has been a lack of understanding of the underlying biochemical basis. This is not surprising because the exact nature of the air ions has not been defined by those concerned. Consequently, there has been no investigation of the interaction between well defined ionized air species and biological systems of different degrees of complexity, which could have provided the basis for understanding the possible biological impact. Recently, however, experiments have been reported by Kellogg *et al.*<sup>4</sup> which "support the concept that the negative air ions responsible for bacterial death consist solely or in part of hydrated superoxide anions". This conclusion was based on the observation that the enzyme superoxide dismutase (SOD) completely protected bacteria against killing by air ionization. This enzyme is known to remove  $O_2^-$  efficiently by catalysing its disproportionation into hydrogen peroxide and molecular oxygen. The negative air ions in that study were produced by a corona discharge-type negative ion generator.

We suggest caution in adopting this conclusion. The negative ion species generated in air by corona discharge have been identified accurately by mass spectrometry<sup>5</sup>. At atmospheric pressure, in static or dynamic conditions,  $CO_3^-$  is the dominant species produced. Such ions were found to be due to small concentrations of  $CO_2$  in air. The  $CO_2$  apparently reacts with  $O^-$  or  $O_3^-$  to form  $CO_3^-$ . It was estimated that only about 40 p.p.m. of  $CO_2$  is needed at atmospheric pressure to convert all oxygen ions to  $CO_3^-$  species. Superoxide anion,  $O_2^-$ , was detected in small amounts only at a gas pressure lower than 200 torr, a maximum of about 15%  $O_2^-$  being produced at 20 torr.

We know of no published report that  $CO_3^-$  can be converted to  $O_2^-$  in water. We have tested<sup>6</sup> the possible generation of  $O_2^-$  from ionized air in aqueous medium by simple and straightforward chemical assay such as reduction of nitroblue tetrazolium (NBT) to the corresponding formazan<sup>7</sup>. A 5-day exposure of an aqueous solution of NBT ( $10^{-5}$  M) to the ion generator (Modulon Corona discharge-type operated at a maximum discharge current of 0.1 mA) provided no indication of conversion to formazan. Also, no evidence could be obtained of the production of hydrogen peroxide, the product of  $O_2^-$  self-disproportionation

( $k = 4 \times 10^5 \text{ M}^{-1} \text{ s}^{-1}$ , ref. 8) in water exposed to the ion generator (1 ml water, 10 cm distance from the needle, 24-h exposure).

Finally, the negative ion flux in the work of Kellogg *et al.*<sup>4</sup> was  $5 \mu\text{A}$ . This corresponds to about  $3 \times 10^{13}$  electron charges per s or  $1.1 \times 10^{17}$  electron charges per h. Even if all the negative charges produced  $O_2^-$ , and neglecting its decay, this is equivalent to  $1.8 \times 10^{-7} \text{ mol } O_2^- \text{ per h}$ . This differs significantly from  $3 \times 10^{-4} \text{ mol } O_2^- \text{ per h}$  as the stated level of  $O_2^-$  in the same work.

We have no ready explanation for the protection by SOD against bacterial killing by negative air ions observed by Kellogg *et al.*<sup>4</sup>. Only by carefully duplicating their experiments and manipulating the variables in their system could one hope to explain the observed data. Whatever the explanation, however, it is very unlikely to be mediated by superoxide radical anion.

Regarding the general mechanism of action of negative ion generators (which are almost exclusively of corona discharge-type), we find it surprising that no attention has been paid to the striking resemblance between them and electrostatic precipitators. These latter devices, well known in the chemical industry, efficiently collect dust, fumes and mists by charging the particles in an electrostatic field created by negative corona discharge electrodes<sup>9</sup>.

We suggest that the same effects attributed to some undefined small negative air ions could be explained by the electrical field produced by the generation of ions. Such a field could cause, for example, the enhanced migration of microbial cells, reminiscent of electrophoresis, which ends in agglutination or adsorption to the walls, resulting in a lower plate count.

The claimed feeling of well-being produced by ion generators<sup>1-3</sup> could be due to an atmosphere free of aerosols and dirt, cleaned by electrostatic precipitation. Would not any other air-filtration device give the same results?

KELLOGG, YOST AND KRUEGER  
REPLY—We have several points to make in reply to the comments by Rosenthal and Ben-Hur. First, no one has yet definitely characterized the chemical nature of negative air ions. The work by Shahin<sup>1</sup> on the ionic species produced by corona discharge seems quite interesting, and he does clearly identify the predominant negative ion made in his system (at atmospheric pressure) as  $CO_3^-$ . However, his system differs from ours<sup>2</sup> in several ways, including the maximal current used (1 mA compared with our 0.01 mA) and the corona discharge voltage (12 kV compared with our 5 kV). We cannot determine whether these differences would affect the negative ions produced. However, even if our system did make  $CO_3^-$  as the principal negative ion species, Shahin's work does not preclude the production of  $HO_2$ , which as an uncharged species would go undetected by mass spectroscopic methods, and which would give rise to  $O_2^-$  in solution.

We do know of a number of studies that support the  $O_2^-(H_2O)_n$  negative air ion concept. For example, Mohnen<sup>3</sup> summarized his work as follows: "An attempt has been made to determine theoretically a reaction scheme to explain the formation of negative small ions in the troposphere and lower stratosphere. The terminal ions are found to be hydrated  $O_2^-$  and  $CO_4^-$ . The degree of hydration depends on temperature, and the mean number of water molecules attached to those ions is of the order of 3 or 4. As soon as the water vapor concentration is less than the concentration of carbon dioxide (about 8 km), the terminal ion is found to be hydrated  $CO_4^-$ . The reaction scheme is based on measured and reasonably estimated reaction rate constants determined by using U.S. standard atmosphere for the neutral gas composition." Regardless of the identity of negative ions in air, this does not preclude their transformation to other ions, such as  $O_2^-$  on addition to solution. Our data, which showed strong protection against negative ion bacterial kill by superoxide dismutase (SOD), but not by denatured SOD, strongly indicated  $O_2^-$  involvement in this negative ion effect, which occurred whether one considers negative air ions as  $O_2^-(H_2O)_n$  or not.

The negative air ion system used by Rosenthal *et al.*<sup>4</sup> to test for  $O_2^-$  production, by looking for nitroblue tetrazolium (NBT) reduction, or  $H_2O_2$  accumulation, had several gross inadequacies. They neither grounded, nor even stirred, their target solutions and could not in fact even demonstrate a bactericidal effect of negative air ions, an effect repeatedly confirmed in numerous published reports. Our own work has shown that the effect of negative ions on NBT gives results that seem neither simple nor straightforward. We found that although negative ion treatment did not cause reduction of NBT to the formazan, it did cause the NBT solution to change spectrally, while concomitantly losing its susceptibility to reduction to the formazan by dithionite. Although SOD completely prevented this effect, we also found that denatured SOD, and even bovine serum albumin, gave complete protection. Our results with NBT, although unexplained, offer no evidence either for or against superoxide involvement in negative air ion effects.

Similarly, the failure of Rosenthal *et al.* to find evidence for  $H_2O_2$  production in solutions exposed to negative ions does not in any way argue against  $O_2^-$  involvement. They failed to understand that one cannot simply 'add' negative charges indefinitely to a target solution, and as their system consisted simply of  $H_2O$  exposed to an ion generator without grounding, or even stirring, one would not expect to find sufficient  $H_2O_2$  accumulation for measurement by even the most sensitive methods, let alone less sensitive chemical methods such as the iodometric that they used.

We apologize that we did inadvertently give an incorrect value for the maximal possible flux of  $O_2^-$  in our system— $0.18 \mu M h^{-1}$  gives a correct estimation of this flux. Over a 5-h period, this gives a ratio of  $\approx 1.4 \times 10^{10}$  negative ions per bacterium. Although the mechanism of bacterial kill remains obscure, it does not seem to occur by agglutination due to electrostatic effects, because early in our experimental series we observed no agglutination of samples in direct microscopic examination. Furthermore, previous studies using polonium-210 or tritium as ion sources have also demonstrated bacterial kill, despite having a field substantially lower than that seen in corona discharge generators<sup>5</sup>. Earlier work using corona discharge generators<sup>6</sup> found a reversal of damage to cells on exposure to intense visible light, an effect which should not occur with agglutination. Finally, the time required for cell death was much less than the minimal time for agglutination predicted by the von Smoluchowski equation<sup>7</sup>. Many other studies have shown the varied biological activity of negative air ions<sup>8-13</sup>, so the suggestion by Rosenthal and Ben-Hur that all negative ion effects are derived from an electric field or electrostatic pre-

cipitation effects appears at odds with the experimental facts of the literature.

## Role of $PGE_2$ in anion exchange in gastric mucosa

IT has been suggested by Schiessel *et al.*<sup>1</sup> that a prostaglandin ( $PGE_2$ ) increases  $Cl^-HCO_3^-$  exchange in gastric mucosa, thereby protecting surface cells against excessive back-diffusion of  $H^+$  from the lumen. Their evidence is necessarily indirect, because it is not known whether such exchange occurs at the nutrient membrane of the surface cell (as demanded by their hypothesis) or, indeed, whether exchange diffusion is a characteristic of this cell type. The authors do show an increase in  $Cl^-$  fluxes across the isolated mucosa due to  $PGE_2$ , and because anion exchange is rather nonspecific in this preparation<sup>2</sup>, as in red blood cells<sup>3,4</sup>, it is reasonable to suppose that exchange of  $Cl^-$  for  $HCO_3^-$  is also increased.

The authors, however, are guilty of a logical *non sequitur*: they deduce that  $PGE_2$  increases exchange of cell  $Cl^-$  for nutrient  $HCO_3^-$  from a negative finding, that  $PGE_2$  does not affect the depression in nutrient to secretory  $Cl^-$  flux due to the removal of secretory  $Cl^-$  (trans-concentration effect<sup>5</sup>). Exchange of  $Cl^-$  across the epithelium requires a suitable partner anion, yielding a null electrical current. In the secretory solution, the authors use replacement anions (isethionate, sulphate) which do not exchange for  $Cl^-$ , and this fact cannot be altered by a drug such as  $PGE_2$ .

The criticism here raises a pertinent question: does a modest level of  $HCO_3^-$  in

the secretory solution reduce the trans-concentration effect, and does  $PGE_2$  then further reduce the effect? Evidence on this question would bear more directly on the authors' hypothesis.

- Heinz, E. & Durbin, R. P. *J. gen. Physiol.* **41**, 101-117 (1957).

SCHIESEL *ET AL.* REPLY—We acknowledge the validity of the argument that  $PGE_2$  cannot alter the trans-concentration effect because replacement anions which do not exchange for  $Cl^-$ , were used in the secretory solution, and we were aware of that fact. In these experimental conditions, however, failure of  $PGE_2$  to affect  $J_{Cl^-}$  (the flux of  $^{36}Cl^-$  measured from nutrient to secretory solutions) more than about the 50% usually found in control experiments in our laboratory suggests that the  $PGE_2$  does not affect either of the remaining components of  $Cl^-$  flux—the active or diffusional components. An unfortunate phrasing of the sentence describing our findings may have led to the misunderstanding that we believed these experiments rigorously excluded the possibility that  $PGE_2$  affects exchange diffusion of  $Cl^-$ .

We agree that much of the evidence for our hypothesis is necessarily indirect. The finding that  $PGE_2$  did not sustain  $Cl^-$  flux in metiamide-inhibited tissues when  $HCO_3^-$  was absent from the nutrient solution supports this hypothesis, however. It is also possible that  $PGE_2$  causes an increase in  $Cl^-$  permeability without change in exchange diffusion of  $HCO_3^-/Cl^-$  exchange.

The suggested experiments would be interesting, but in our opinion difficult to interpret and not definitive in excluding an effect of  $PGE_2$  on exchange diffusion of  $Cl^-$ . If all three components of the  $Cl^-$  flux are operative when a suitable exchangeable anion (not  $Cl^-$ ) is in the secretory solution, stimulation of  $Cl^-$  flux by  $PGE_2$  would not specifically define the effect of  $PGE_2$  on any of the three components of  $Cl^-$  flux. Conversely, failure of  $PGE_2$  to stimulate  $Cl^-$  flux in these conditions might be interpreted as evidence that either a direct  $Cl^-Cl^-$  exchange at the secretory membrane is required for the  $PGE_2$  effect or that the non- $Cl^-$  anion inhibited the effect of  $PGE_2$ .

## BOOK REVIEWS

## Tertiary sector of the science industry

Edward Shils

THE activities of thinking and observing which are involved in the pursuit of scientific knowledge occur in a setting of many other activities and institutions which are not themselves scientific knowledge but which are indispensable to it. These include the intellectual relationships among individual scientists, within institutions, within and between countries; the traditions of institutions — such as laboratories — in which scientific work is done; the organs and institutions through which scientists communicate the results of their research; and the processes through which problems are selected and knowledge is sifted, rejected, affirmed, extended, elaborated and revised. It is in these actions and places that the “public” character of science is exhibited. They constitute what has come to be known as “the scientific community”, a complex made up of as many scientific sub-communities as there are fields of specialization, and institutions and countries in which scientific work is done.

In addition, there are the institutions and arrangements which bring scientific traditions into the focus of attention of young persons who might become scientists, and those processes by which aspirant scientists are inducted into the intellectual and moral discipline of scientific work. Since scientific work requires apparatus and time free from other obligations, the institutional arrangements whereby scientists are enabled to live and to have what they need to do scientific work are likewise parts of this immediately necessary complement to the advancement of scientific knowledge.

Around all this there have grown up a large number of supplementary activities which are not integral or immediately necessary to the pursuit of scientific knowledge and its incorporation, by application, into technology. Among these are the historiography of science and medicine and of the technology used in economic life and warfare, systematic analysis of the logical and epistemological structure of scientific propositions, reflection on the moral and other merits and demerits of scientific knowledge and of technology in

*A Guide to the Culture of Science, Technology, and Medicine.* Edited by Paul T. Durbin. (Free Press/Collier Macmillan: 1980.) \$45, £30.

their many forms, the sociological study of the structure of scientific communities and of particular scientific institutions, and discussions about whether and how science should be governed by authorities outside itself. Some of this penumbral intellectual effort has been carried on by academics. Some of it has become established in academic institutions as parts of existing disciplines such as history, philosophy and sociology. Some is part of journalism and of amateur scholarship.

Finally, at some distance from immediate involvement with the pursuit of scientific knowledge, there are the ramifications of science into the way of life and outlook of the ordinary members of society — its impact on their moral notions and conduct, their cosmological and religious beliefs, their conceptions of mankind and the world, and their ideas about and knowledge of science itself.

All of this vast complex may be called “the culture of science”. It is an immense subject, deserving of studious attention because it permeates so much of modern civilization.

*A Guide to the Culture of Science, Technology and Medicine* is a collaborative attempt to summarize the state of knowledge regarding the culture of science. It is a thick volume of nine parts, ranging in length from 30 to about 60 pages. The parts deal with the history of science, written by Arnold Thackray; the history of technology, by Carroll Pursell; the history of medicine, by Gert Brieger; the philosophy of science in its “historical, social and value aspects”, by Alex Michalos; the philosophy of medicine, by H. Tristram Engelhardt and Edmund Erde; the sociology of science and technology, by Jerry Gaston; medical sociology and science and technology in medicine, by Linda Aiken and Howard Freeman; and science policy studies by Diane Crane. Each essay is accompanied by a long and excellent bibliography.

As is inevitable with such a work, the outcome is very uneven. Most noticeably, the quality of the contributions is unrelated to their length. Two of the least valuable — those on the history of technology and the

philosophy of science — are respectively the shortest and nearly the longest in the volume. The long essay on the philosophy of science contains less about the culture of science than any of the others; it is a series of mechanically assembled summaries and bibliographical references, some of them patently second-hand. Some, but not all of the defects of this particular essay are attributable to the author; they are also due to the dreary literature which he has to summarize, a literature which is self-contained, having little to do with what scientists do and know.

It is not accidental that the richest contributions are those by Brieger, by Engelhardt and Erde, and by Aiken and Freeman. Each of these essays benefits from the authors’ intimacy with medical practice and biomedical science, and from the long traditions of learning and reflection by physicians and biomedical scientists; in these there is an exceptional awareness of moral issues. Exceptional, because although the contributors to the volume were apparently enjoined by the editorial board to pay particular attention to moral issues and questions of “values”, most of the authors deal with them in a perfunctory way, as if they were acting under orders and did not have their heart in it. It is only in those essays dealing with medicine — and in Mitcham’s essay on the philosophy of technology — that the moral or “value” problems are treated as genuine issues which practitioners and investigators are under compelling obligation to reflect upon, and to take into account in their actions.

How are we to explain this difference between the humdrum and insightful character of some of these essays and the lively realism of others? The answer to this seems to me to lie in the fact that, for some of the authors, the “culture of science, technology and medicine” is something to be written about from the outside, as an academic quasi-discipline with its own self-justifying traditions. They regard it as something to be studied and written about, but not as something in which they participate. This bespeaks a deficiency in their understanding of the concept. They do not really see the literature of their subjects as parts of the “culture” — despite the title of the book to which they have contributed. The centrality of scientific knowledge to the “culture of

Edward Shils is Professor of Sociology and Social Thought at the University of Chicago and editor of *Minerva*. His most recent book is *The Calling of Sociology* (University of Chicago Press, 1980).

science" seems to have escaped some of the contributors to this book, not least the sociologists among them.

Here, a word should be said about the contributions of sociology to the present volume. In the essay which deals with medical sociology and science and technology in medicine, the authors devote less than one-fourth of their space to the former and, although they deal with it appreciatively, they see that it touches only spottily on their topic. They point out that it is guided by the tradition of sociology as an academic discipline. What they are indicating is that medical sociology, with all its merits, has not really become part of the culture of science, technology and medicine. The same must be said about the way in which the sociology of science and technology is presented here.

The editors themselves must bear some of the onus for this faulty understanding of the culture of science. Otherwise how could they have omitted any treatment of the impact of scientific knowledge on the

outlook and conduct of ordinary members of modern societies? There is nothing in the book about that. Nor is there anything about scientific education. And, except for passing comments in the essays on the history of science and medicine, there is no serious consideration of the process of the growth of scientific knowledge. The editors have found the right name for their subject but they have not found the subject to which to apply it.

In the preface it is stated that "more than anything else, the volume should be useful to teachers of interdisciplinary courses in technology and values or science and society". If their expectation is realized, it will help to maintain such courses of study in their present superficiality and in their arbitrary and distorted conception of their subject. This book has considerable value but it is not a guide for those who are too isolated for their own good from science, technology and medicine, and who do not understand their own peculiar place in its culture. □

presented in this review, unfortunately, is based on the authors' own work, with the consequence that the chapter is too short to cover these interesting viruses in sufficient depth.

The final contribution is a review on the prospects in human retrovirus research. It does, however, present a somewhat unusual perspective as it is more cautious than previous reviews on the subject. The chapter is well balanced and covers the appropriate material comprehensively.

Overall, the book is an adequate compilation of many useful reviews. What is missing, however, is a final section that brings together the diverse ideas and information — instead of leaving the chapters as separate entities — and a discussion of the direction that future work in this field should take. It is also rather unfortunate that, at the time of completion of the book (early 1979), information on molecular cloning studies and structures of proviruses was still scanty, for additional material on these subjects would improve the book. This kind of drawback is perhaps inevitable in such multi-author reviews covering fast-moving areas of research. Nevertheless, this book should stand as a good source of references. It should also be of value to biochemists with a special interest in retroviruses and to pre- and postdoctoral fellows entering the field. □

## Retrovirus research

Tak W. Mak

*Molecular Biology of RNA Tumor Viruses.* Edited by John R. Stephenson. Pp. 528. (Academic: 1980.) \$49.50, £34.20.

THE momentum that was given to retrovirus research by the discovery of reverse transcriptase is still strong. Today, ten years after that discovery, the field remains one of the most active areas in biology. The book, a collection of 12 reviews by as many groups, is an attempt to take stock and evaluate the progress in the field. In general, the reviews are informative though a few chapters are somewhat narrow in that they tend to dwell on the authors' own work. A more important criticism, however, is that the choice of topics suffers from lack of an overall balance that would accurately reflect the efforts in different aspects of retrovirus research. For example, the reviews tend to emphasize mammalian retroviruses, with a strong accent on murine type-C viruses, while omitting much of the avian viruses and their genetics.

The book begins with a good account of the historical development of retrovirus research, from the discovery of Rous sarcoma virus to the present. The three chapters which follow all deal with mammalian type-C retrovirus genes and their transmission. The first is a summary of the efforts to delineate further evolutionary relationships among primates and mice through studies of their endogenous retrovirus sequences. The next, on murine endogenous type-C viruses, is a comprehensive account of the

genetics and regulation of murine type-C retroviruses. It contains many helpful tables to aid readers in understanding this complicated field. The third of these opening contributions is on the integration and transmission of exogenous murine type-C virus. It contains some interesting information on germ line integration of exogenous virus. However, it seems rather brief and repetitive after the two preceding, rather ampler, chapters.

The next two contributions are on transforming viruses and retrovirus genomes, respectively. They are both useful reviews. They complement each other well and are presented at an appropriate level for such a volume. That which deals with retrovirus genomes, however, is too short to cover the genome structures of both avian and murine retroviruses. Expansion of this chapter or addition of another article to include more on avian retroviruses and the biochemistry of retroviruses would have been desirable.

The seventh and eighth chapters are on type-C viral proteins and their primary structures. They contain an in-depth look at the proteins of type-C retrovirus and would be useful for investigators interested in the subject. Next come two contributions on reverse transcriptase and heteroduplex mapping — both of which are informative and contain detailed surveys of reverse transcriptase enzymology and heteroduplex mapping of viral genomes. The eleventh chapter is a discussion of type-B and type-D retroviruses. Most of the information

## Evolving theories

Adrian Friday

*Phylogenetic Patterns and the Evolutionary Process. Method and Theory in Comparative Biology.* By Niles Eldredge and Joel Cracraft. Pp. 349. (Columbia University Press: 1980.) \$27.50, £15.50.

ELDRIDGE and Cracraft's central theme is that estimates of the pattern of evolutionary history logically precede the making of hypotheses about the process of evolution.

Estimation of the pattern of evolutionary relationships is inevitably carried out by the comparison of similarities between organisms. To Eldredge and Cracraft, shared similarities do not all have equal status in this enterprise but, following the ideas of the late Willi Hennig, a way of organizing such information is to construct a series of nested sets each characterized by at least one evolutionary innovation (Hennig's "synapomorphy"). That these are innovations emphasizes to the authors the importance in such analysis of interpreting the pathway of change in biological characters. Decisions about the sequence of change can often be difficult

to make, but the stark alternative interpretation of the pattern of differences between organisms as a static, instantaneous phenomenon is clearly not one likely to appeal to evolutionary biologists. To quote Eldredge and Cracraft (p.55): "The concept of nested sets of synapomorphy makes sense only if it is assumed that change has taken place . . .".

The so-called "problem of homology" is presented as not being a problem when phylogenetic homologies are equated with the evolutionary innovations defining sets. Accordingly, evolutionary convergence is interpreted as non-homologous similarity: the sceptical might regard this as more a definition than a solution.

For Eldredge and Cracraft, a diagram summarizing set membership is a "cladogram" and includes no designation of ancestral versus descendant organisms. If such additional conjectures are made, the diagram then becomes a phylogenetic tree. The difference is seen as an important one: the cladogram being the more general statement. However, no mention is made of the valuable work of G.F. Estabrook which defines these concepts more precisely from a rather different viewpoint.

The authors present the structure of a cladogram as subject to rejection and replacement by an alternative hypothesis. In this way hypotheses of set membership can be corroborated. Rejection is achieved by the examination of more characters. Where these contradict the original partitioning, they may do so in concerted fashion and force a re-examination, not only of the old scheme of hierarchies, but also of our biological understanding of the characters used to define them. A statement that: "The criterion of parsimony specifies our acceptance of the least rejected hypothesis" (p.70) may seem unexceptionable to many, but: "In evolutionary terms, therefore, we prefer the cladistic hypothesis which minimizes convergence" (also p.70) appears unfortunate in view of the authors' otherwise clinical view of parsimony as an inevitable component of the hypothetico-deductive method rather than a principle of the evolutionary process.

In the final chapter the separate nature of microevolution, speciation and macroevolution is emphasized (with due acknowledgement to the ideas of Sewall Wright and S. N. Salthe). On this subject the book becomes repetitious and risks losing its momentum in nested reappraisals of previous sections. Certainly, a reading of such recent books as R. C. Lewontin's *The Genetic Basis of Evolutionary Change* (Columbia University Press, 1974), M. J. D. White's *Modes of Speciation* (Freeman, 1978) and S. M. Stanley's *Macroevolution* (Freeman, 1979) reinforces the lack of a unified theory underlying the events of evolution.

Ironically, the conflict between pattern and process can be brought out by con-

sidering the approach of population geneticists to the estimation of kinship relationships using gene frequency data measured in human populations, clearly a "microevolutionary" study (an example is given in E. A. Thompson's *Human Evolutionary Trees*; Cambridge University Press, 1975). This type of estimation is a statistical exercise involving the prior construction of a probabilistic model of change. When we attempt to apply such a methodologically rigorous approach to anatomical characters it is difficult to frame a plausible model for the process.

What Eldredge and Cracraft's book

suggests to me, in defiance of their declared theme, is that our lack of a model for the relevant processes of evolution hampers the convincing reconstruction of the pattern of evolutionary relationships. The majority of readers would probably not agree. In any case, the book is strongly recommended to allies and opponents alike. It solicits underlinings and exclamation marks and is mostly elegantly argued and enjoyable.

## Humphry Davy and geological conundrums

G.Y. Craig

*Humphry Davy on Geology: The 1805 Lectures for the General Audience.* Edited by R. Siegfried and R.H. Dott. Pp.169. (University of Wisconsin Press: 1980.) \$17.50, £9.

Sir Humphry Davy

HUMPHRY Davy, chemist and inventor, lectured on a variety of scientific subjects at the Royal Institution in London between 1801 and 1812. From 1805 onwards he gave a course of ten lectures in geology. Happily, full hand-written notes on eight of his lectures have been preserved, and with two further transcripts by a copyist now provide the only complete lecture course known among Davy's surviving papers.

In their introductory chapter the editors outline Davy's career and comment on his geological philosophy. Davy himself explains his stance in the first lecture:

Geology, perhaps more than any other department of natural philosophy, is a science of contemplation. It requires no experience or complicated apparatus, no minute processes upon the unknown properties of matter. It demands only an inquiring mind and senses alive to the facts

almost everywhere presented in nature. As it may be acquired without much difficulty, so it may be improved without much painful exertion.

Almost a century later Sir Archibald Geikie commented in his biography of Murchison that it also required a stout pair of legs!

Davy's style is clear, his writing elegant, his criticisms courteous, and throughout he reveals the caution typical of the chemist. The first four lectures, excluding a general introductory lecture, are largely concerned with a review of earlier theoretical speculations, ranging from Greek philosophers to late-eighteenth century writers. In the following six lectures he describes rocks and outcrops, both from his own observations and from those of the other naturalists. Conundrums are many, resolutions are few. Why should limestone stick more firmly to sandstone than to schist? There is a report of fishes in basalt! Is coal formed by heat from vegetable matter?—yet the strata above and below don't appear to have been subjected to heat. Sensible personal observations blended with second-hand reports, contradictory theories and a belief in a purposeful progression of life inevitably lead to difficulty. Davy does not attempt to develop an independent theory of his own, but with the critical and perhaps slightly superior view of an experimental chemist has as much to be wary about. Since he is not prepared to be a Neptunist, and is unwilling to be a Plutonist, he finds himself on occasions in an impossible position:

All the facts seem to render it probable that the basaltic rocks usually found in alternation with the common secondary rocks cannot be of igneous origin. But the proposition of the impossibility of the formation of this substance by fire must not be advanced.

Davy was not the first lecturer in geology in Britain; he was preceded by Walker at Edinburgh and by Beddoes at Oxford and Bristol. And although there was no

## FROM DNA TO PROTEIN: The Transfer of Genetic Information MARIA SZEKELY

This is the first textbook which discusses gene structure on the basis of recent discoveries of overlapping and split genes and which genetic information can be encoded into the genetic material and how it can be transferred to other materials.

A perfectly up-to-date account of our present knowledge of the structure and expression of genes in prokaryotic and eukaryotic organisms and the only available text showing the correlation between the structure and function of nucleic acids.

## HUMAN REPRODUCTION AND DEVELOPMENTAL BIOLOGY D. J. BEGLEY, J. A. FIRTH and J. R. S. HOULT

An integrated approach to describe the cellular and physiological processes of human reproduction and embryological development in relation to their underlying mechanisms and to their practical applications in medicine. The book combines anatomy, biochemistry, physiology and pharmacology, making it more suitable for modern preclinical and human biology courses.

February, £20.00, 0 333 23423 5

## GYNAECOLOGICAL CYTOLOGY

MATHILDE E. BOON and  
METTE LISE TABBERS-  
BOUMEESTER

Dr Boon and Dr Tabbers-Boumeester have, over the past ten years, developed the course in diagnostic cytology which was first given in Leiden in 1969.

In this volume they present their insight into both the study of diagnostic cytology, and into the teaching of this increasingly important subject. To illustrate the modern concepts of cytopathology, examples of more advanced approaches are included: as well as scanning and electron microscopy there are details of DNA measurements, morphometry and immunopathology.

elementary textbook as we know it at the time, Playfair's *Illustrations of the Huttonian Theory* was certainly available. It would be interesting to know the names of the people who attended Davy's classes and the influence that he had on them. We know for instance from Geikie's biography that R.I. Murchison attended Davy's class in 1812 and that in 1823 Davy encouraged Murchison to go up to London and take some lectures in chemistry, etc. Davy's further irresistible bait was that he would soon get Murchison into the Royal Society (Davy was at that time its President!). Perhaps then Davy's greatest contribution to geology was to persuade Murchison to

abandon fox-hunting and take up geology instead.

Geologists and historians will be grateful to the editors for producing this book and continuing the tradition of academics in the mid-western United States in providing, indeed specializing in, transcripts and facsimile copies of the works of the late-eighteenth and early-nineteenth century philosophers of the Earth. Future historians of the history of science will no doubt one day wish to consider the reason for this phenomenon.

G.Y. Craig is Professor of Geology at the University of Edinburgh.

## Cellular regulatory mechanisms

John Mowbray

*Principles of Metabolic Control in Mammalian Systems.* Edited by R.H. Herman, R.M. Cohn and P.D. McNamara. Pp.670. (Plenum: 1980.) \$35, £22.05.

THE editors of this large book are also the main contributors as authors or co-authors of 11 of the 15 chapters. Their aim, according to the preface, is to discern basic regulatory principles and to embody these in a theoretical approach which can be applied to any set of metabolic reactions. Anyone conversant with the development of metabolic regulation in recent years could be forgiven the thought that such an attempt is premature; close reading of the resulting volume has unfortunately done nothing to dispel my prejudice in this respect. This does not mean that the work should be dismissed out-of-hand, for there is a patent need to collate and review critically the diffuse literature on cellular regulation so that the various arguments may be widely appreciated and tested.

The subject is not one for those without a basic grounding in biochemistry, and yet many of the chapters are padded out with rather large amounts of elementary textbook information. The second chapter, for example, discusses metabolic networks from a non-linear, non-equilibrium, thermodynamic point of view in the first part and defines, as in a primer, hydrophobic, electrostatic, covalent and van der Waals interactions in the second part. In similar vein the special purpose of the book receives little or no contribution from the chapters on enzymes and coenzymes, protein synthesis, DNA replication and the cell cycle, membrane enzymes and membrane structure. All of these topics are better presented (there is a noticeable dearth of diagrams in this volume) in most textbooks for the beginner, and are readily accessible in expert reviews or monographs for the more

advanced reader. On the other hand, a topic not well covered as yet, protein degradation, is presented in a straightforward account with the methodological reservations adequately expounded.

Of the chapters devoted to regulatory mechanisms, the opening chapter in the book develops the hierarchical classification of metabolic processes from which the authors believe important principles can be deduced. The lists and tables are informative, albeit less than comprehensive. In a later contribution, modulation of enzyme activity is discussed without achieving the penetration of specialist monographs like those by Newsholme and Start (Wiley, 1973), or Ferdinand (Wiley, 1976), and it lacks the breadth of some recent reviews. The account of feedback/forward on complex pathways such as glycolysis strikes me as difficult to follow without the aid of diagrams unless one is already familiar with the examples. The chapter "Secretion Mechanisms" is a good, clear account with sufficient references for further reading, and that on the role of compartmentation is well written and nicely balanced with examples taken from key processes. Finally, the chapter dealing with hormone mechanisms has an interesting section on comparative biochemical endocrinology which is perhaps too complex for the novice, and a comprehensive though somewhat uncritical treatment of fast-acting hormones. By contrast the treatment of steroid hormones is cursory in the extreme, spoiling what is otherwise one of the better chapters.

In the end, while there are selected chapters one can recommend to one's students, this is a book for the specialist who can win the grains of very real effort the editors have sown from the chaff of their self-indulgence.

John Mowbray is a Lecturer in Biochemistry at University College London.
